Electrical Mobilities and Tracer-diffusion Coefficients of the Na and Tl Ions in the Molten (Na — Tl)NO₃ System

SANDRO FORCHERI and VITTORIANO WAGNER

Electrochemistry Group, Euratom C.C.R., PETTEN—N.H. (The Netherlands)

(Z. Naturforsch. 22 a, 1171—1176 [1967]; received 16 March 1967)

The ionic mobilities and the diffusion coefficients of Na and Tl in the (Na — Tl)NO₃ system have been determined by means of a zone electromigration and diffusion technique. The most significant feature of the Na mobility isotherm is its rapid variation with composition in the NaNO₃ rich region.

The diffusion coefficients of both cations have been found to depend rather weakly on composition. The electrical and diffusional mobilities of both cations show trends opposite to that of the fluidity.

These results are discussed in terms of the anion polarization model. Equilibrium properties of molten binary mixtures with a common anion have been successfully correlated to the anion polarization effect. A straightforward test of this effect has been given for molten chloride binary mixtures by means of N.M.R. measurements. Concerning transport processes, recently Latyé observed that some electrical properties (conductivity and ion mobilities) of the (Li — K)Cl system are consistent with the anion polarization model.

In molten alkali nitrate binary mixtures, systematic deviations of the conductivity isotherms from additivity, together with positive deviations of the corresponding activation energies, have been considered as a consequence of the anionic polarization due to the difference of the cationic fields.

More detailed information on the factors affecting the transport properties can be obtained by determining the electrical and diffusional ionic mobilities. In this work the (Na — Tl)NO₃ system is investigated by means of tracer zone electromophoresis and tracer diffusion measurements (Na²² and Tl²⁰⁴).

After their first application to molten salts by Arnikar, who used asbestos paper as a support, zone electromophoresis methods have been frequently used in this field. Recently the accuracy of the measurements on glass fiber paper has been greatly improved. The method we have used in this work is based on the utilization of porous ceramic thin layers, in powder or in fritted form, as a support for the molten electrolyte in the electromigration and diffusion experiments. The electrical conductivity and density of the (Na — Tl)NO₃ system have been recently determined. The present experimental results of ionic mobilities and of tracer diffusion coefficients are compared to some viscosity data which became lately available.

Experimental

Reagent grade NaNO₃ and TlNO₃ were purified by recrystallization from aqueous solutions. Na²² and Tl²⁰⁴ were supplied by the Radiochemical Center Amersham, Buckinghamshire, England.

Although with zone electromophoresis it is possible to determine the ionic mobility and the diffusion coefficient simultaneously, from the displacement and the widening of the labelled zone, nevertheless separate experiments are more suitable.

The preparation of the porous layers, the assembly and the procedure of the electromigration experiments were previously described. The mobility of the

two cations was determined simultaneously at each composition by labelling two or more points of the strip (length \( \sim 15 \text{ cm} \), width \( \sim 0.6 \text{ cm} \)) with a small quantity (several tenths of mg) of Na\(^{22}\)NO\(_3\) and of Tl\(^{204}\)NO\(_3\).

The ionic mobility \( u_w \) of a cation is proportional to its zone mobility \( u_z \),

\[
u_w = K u_z \quad (K > 1)
\]

where \( u_z \) is the rate of the displacement of the labelled zone in unit apparent electrical field \( (\Delta V/\text{length of the strip}) \), and the factor \( K \) accounts for the obstruction of the particles of the porous support to the ionic migration. If this correction factor is defined as the inverse of the obstruction factor derived by CRAWFORD and EDWARD \(^{16}\) for paper electrophoresis:

\[
K = R_p \frac{\chi}{p/d}
\]

where \( R_p = \text{resistance of the strip per unit length}, \chi = \text{specific conductivity of the melt}, p = \text{salt weight per unit length}, d = \text{density of the melt}, \) then

\[
u_w = \left(\frac{\chi}{d}\right) \left(\frac{p l}{q}\right)
\]

where \( l = \text{the measured displacement of the labelled zone}, q = \text{ionic charge passed through the strip}.\)

The precision of the measurement of \( u_w \) depends essentially on the accuracy \((\pm 2\%)\) of the determination of the displacement \( l \), (usually several centimeters) \(^{14}\).

According to formula (3) \( u_w \) can be determined without any knowledge of the \( K \) factor. On the contrary to measure diffusion coefficients from the gaussian activity distribution on the strip \(^{15}\) this parameter must be determined by means of a measurement of \( R_p \) [see Eq. (2)]. The assembly used in the diffusion experiments is shown in Fig. 1. \( R_p \) is measured by means of two platinum electrodes placed in contact with the porous layer. The diffusion coefficient was calculated by the formula:

\[
D = - \left(\frac{1}{2,3}\right) \left(\frac{K}{4 S t}\right)
\]

where \( S = \text{slope of the plots log activity vs. the squared distance from the gaussian centre} \) (Fig. 2), \( t = \text{time of the diffusion experiment} \).

The accuracy in the measurement of \( D \) depends mainly on the precision of the determination of the \( K \) factor and of the slope \( S \). \( K \) was usually determined at \( \sim \pm 1.5\% \); in the case of the Tl\(^{204} \) (\( \beta \)-emitting isotope) \( S \) was determined at \( \sim \pm 2\% \); in the case of the Na\(^{22} \) (\( \beta - \gamma \)-emitting isotope) \( S \) was determined at \( \sim \pm 4\% \).

The scanning of the strip was performed according to a method previously described \(^{17}\).

The temperature during the experiments was measured by means of a calibrated Cr–Al thermocouple, placed very near to the strip. After each experiment the composition of the molten mixtures was controlled by analysis.

In a preliminary investigation conductivity determinations of alumina porous thin layers impregnated with various molten nitrates (alkali as well Ti and Ag nitrates) were carried out. The results obtained showed that \( K \) (usual value 1.3 \( \div \) 1.9) is only a function of the absorbance of the system (salt volume/weight of support) \(^{18}\) (for more general informations on this topic see Ref. \(^{19}\)).

Results and Discussion

Ionic mobilities

Equation (1) expresses external mobilities (frame of reference = the wall). When discussing ion mobility isotherms of binary systems with a common anion, it seems more suitable to consider internal quantities (frame of reference = the anion).

To obtain the internal mobility, \( u \), the following equation must be employed:

\[
U = U_{w} + U_{w} \chi_{03} \quad (5)
\]

in which:

\[
u_{w, NO_3} = \frac{A}{F} - X_{Tl} u_{Tl,w} - X_{Na} u_{Na,w} \quad (6)
\]

where \( X_{Na} \) and \( X_{Tl} \) are the molar fractions of the NaNO\(_3\) and TiNO\(_3\).

In Table 1 the internal mobilities and equivalent conductivities at 316 °C are reported. Fig. 3 is a plot of \( u_{Na} \), \( u_{Tl} \) and \( A \) vs. the composition of the mixture.

The most striking feature of the mobility diagram is the rapid decrease of the mobility of the smaller ion, (Na), at increasing concentrations of the larger cation. From the data reported in the literature on (Na – K)NO\(_3\) \( ^{11,21} \), (Li – K)NO\(_3\) \( ^{22,23} \), (Li – K)Cl \( ^{5} \), and (Li – K)SO\(_4\) \( ^{24} \), it can be inferred that this behaviour is not unusual in molten systems (if internal quantities are considered). In the (Na – Tl)NO\(_3\) system the variation of the mobility of the larger cation with composition is smaller than in the cases quoted above.

As was pointed out in a previous paper \( ^{7} \) the trend of the electrical conductivity and of the Na mobility could be well accounted for, at least qualitatively, by the LUMSDEN polarization model. Moreover, in agreement with LAITY's \( ^{5} \) results in chloride melts, the mobility of the larger cation rises only slowly at increasing concentrations of the smaller cation.

Let us define the function

\[
P = \frac{P_X}{P_{0,5}} = \frac{X_{Na} \cdot (1 - X_{Na})}{0.25}
\]

(where \( X_{Na} \) is the molar fraction of NaNO\(_3\)) as the ratio between the chance of finding the ion triplet Na·NO\(_3\)·Tl at \( 0.5 < X_{Na} < 1 \) and the chance of finding it at \( X_{Na} = 0.5 \) (the ions being supposed randomly distributed \( ^{25} \)). The increase of the sodium

mobility, \( u_{Na,X} \), in the range \( 0.5 < X_{Na} < 1 \), may be related to the decrease of the function \( P \), by means of a relationship of the type

\[
u_{Na,X} = u_{Na,1} - (u_{Na,1} - u_{Na,0.5}) P
\]

where \( u_{Na,1} \) is the sodium mobility in pure NaN0\(_3\) and \( u_{Na,0.5} \) the mobility in the equimolecular mixture.

The sodium mobility and the fluidity \( \Phi = 1/\eta \) (\( \eta \) = viscosity) vary in an opposite way (see Figs. 3 and 4).

Fig. 4. Fluidity isotherm of the (Na—Tl)NO\(_3\) system at 316 °C.

Tracer diffusion coefficients

The cationic tracer diffusion coefficients of the (Na—Tl)NO\(_3\) system at 316 °C are reported in Table 2. In Fig. 5 the diffusion isotherms at this temperature in the whole composition range and at 219 °C in the range from 0.0 to 0.3 mole fraction of NaN0\(_3\) are presented.

Table 3 lists some diffusional results on pure TlNO\(_3\) and on a mixture containing 20% NaN0\(_3\) at different temperatures. Fig. 6 presents these results in the form of Arrhenius plots.

The possibility of comparing the obtained diffusion coefficients with those obtained by other workers is limited to the Na\(^{22}\) diffusion in pure NaN0\(_3\). In the range of our measurements (316 °C to 358 °C), the obtained values show deviations from literature data\(^{26-29}\) not larger than 15% (Fig. 7, Table 4).

Table 2. Tracer diffusion coefficients at 316 °C.

Table 3. Tracer diffusion coefficients at different temperatures.

The trend of the diffusion isotherms (Fig. 5), is similar to that in (Na—K)NO₃ 27 and in (Li—K)NO₃ 23. The small positive deviations shown in our case are present also in (Li—K)NO₃ 23, and, more markedly, in (Li—Na)CO₃ 30.

From the Arrhenius plots of Fig. 6, it can be observed that the tracer diffusion activation energies of both cations are nearly equal (4.3 ÷ 4.4 kcal/mole) in pure TiNO₃ as well as in a mixture containing 20% NaN₃. A similar situation was found for the system (Na—K)NO₃ by Lantelme and Chemla 27.

Activation energies for interdiffusion of a number of cations and anions in nitrate environments [(Na—K)NO₃ and (Li—Na—K)NO₃ eutectic], measured polarographically by Francini and Martini 31, 32, were found equal among them. For Na diffusion in pure NaN₃ the calculated activation energy is 5.3 kcal/mole. The corresponding value of Van Artsdalen 26 is 4.97 kcal/mole. It has been observed 5 that the polarization of the common anion, which causes an increased (or reduced) hindrance in the relative cation-anion motion, should have a smaller influence on diffusion than on electromigration. The present results are in agreement with these arguments.

Tracer diffusion coefficients have been usually correlated to the fluidity Φ through the Sutherland-(Stokes)-Einstein relationship:

$$D = \frac{(K/a) (\Phi T/r_{Me}^2)}{7}$$

where $r_{Me}^2$ is the radius of the diffusing particle and the numerical factor $a$ is 6π for large diffusing particles, and 4π for small ones, in the classical formulation, or even smaller according to other theories 33, 34.

Fig. 8 ($D$ vs. $\Phi T/\rho_{\text{Me}'}$) shows that Eq. (7) accounts fairly well for the diffusion of Na in NaNO$_3$ and of Tl in TlNO$_3$ as well as for cation diffusion in other pure univalent nitrates, if an $a$ value of about 4.6$\pi$ is chosen. The tracer diffusion coefficients of foreign ions deviate the more from this behaviour the larger the difference in size between foreign and proper cation. The diffusion coefficients of foreign ions smaller (larger) than the proper ions are below (above), the straight line in Fig. 8 ($a$ values of about 7$\pi$ for Na in TlNO$_3$ and Li in KNO$_3$; $a$ values of about 3.5$\pi$ for Tl in NaNO$_3$ and K in LiNO$_3$).

The dependence on composition of the tracer diffusion coefficients of Na and Tl (Fig. 5), as well as that of mobilities, differs in sign from that of the fluidity (Fig. 4).

From RAMAN spectroscopy evidences, in pure molten univalent nitrates, JANZ 39 pointed out that the metal ion-nitrate interaction, may cause "the time of residence of the cation near the anion to be long compared with the time of the molecular vibration". It can be expected that in mixtures this effect for a given cation would be enhanced or hindered according to the polarization direction. The stand of a cation near the anion will cause a sort of "cooperative act" 30 during the diffusion, which may explain the approximate constance of the diffusion activation energy for all the ions in the same melt, irrespective of the different $a$ values.

Interactions of this type are of major importance for electrical mobilities, the effect of the polarization being in this case magnified because the cations and anions travel in opposite directions.

Finally one can observe that the transport behaviour of (Na — Tl)NO$_3$ is rather similar to that of alkali-nitrate binary systems 7. It seems therefore that the variation of the LONDON dispersion forces between the cations in mixtures which have some influence on the equilibrium properties of this system 40 are not so markedly significant in irreversible processes.

We are greatly indebted to G. Friz (Exchanges Thermaques, Ispra) for the permission to report the fluidity diagram. — We wish to thank J. COLLIN (Chimie Analytique, Ispra) for his help in the analytical problems. — We are also indebted to B. DONATI for his kind technical assistance.
