The effect of 2-phenylindole (2PI) concentration in p-xylene upon the fluorescence decay time was investigated by frequency-domain fluorometry. The fluorescence decay of a dilute (10^{-3} M) 2PI solution in p-xylene at 20 °C is single exponential with the mean decay time τ = 1.87 ns and practically independent of the observation wavelength (λ_{obs}) in the fluorescence band. The fluorescence decay in a highly concentrated solution (6 × 10^{-2} M) is heterogeneous and depends on λ_{exc}. For a given modulation frequency (~ 200 Hz), the fluorescence phase shifts at the longwave observation (440–480 nm) distinctly exceed 90°, thus clearly indicating that the observed (excimer) fluorescence results from a process taking place in the excited state. The fluorescence decays were measured at seven values of λ_{exc} (360–480 nm), and all the results were analyzed comprehensively (τr and τe are equal for all λ_{exc}; the amplitudes are different). The lifetimes of the excimer state is relatively short (~3.5 ns). Radiative (τr) and non-radiative (τe) rate constants for monomer fluorescence of 2PI in p-xylene were determined using appropriate data from photo- and radioluminescence measurements.

1. Introduction

2-Phenylindole (2PI) is the chromophoric core of the DNA-binding probe 4,6-diamidino-2-phenylindole (DAPI) [1–4]. Kubista et al. [5] have shown that 2PI is a suitable model system for DAPI with regard to the almost total agreement between the spectral assignments of DAPI and 2PI. Theoretical considerations about the electronic states of 2PI are applicable to DAPI. Based on experimental investigations and quantum chemical calculations, 2PI was found to have five distinct electronic transitions located between 200 and 350 nm [5]. The first absorption band (340–280 nm) consists of two electronic transitions separated from higher energy transitions.

The molecule of 2PI is polar, and the electric dipole moments in the ground (µg) and excited (µe) states are oriented in the same direction. The values are: µg = 2.01 D (= 6.7 × 10^{-30} C m) [6] and µe = 4.2 D (= 14 × 10^{-30} C m) [7].

It was also found that 2PI forms excimers in p-xylene and n-butanol and the "isoemissive" points show a considerable solvent dependence [8]. Moreover, 2PI is an efficient scintillator and the radioluminescence efficiency, f_{max}, is 0.274 [8, 9].

In this paper we report investigations on the decays of monomer and excimer 2PI fluorescence in p-xylene at 20 °C by frequency-domain fluorometry.

2. Experimental

2PI (Fluka AG, purity >99%) was used without further purification, p-xylene (Aldrich) was HPLC grade.

Frequency-domain measurements were performed on an instrument described previously [10, 11]. The light source was a synchronously pumped rhodamine 6G dye laser, cavity dumped at 3.76 MHz and frequency doubled to provide ultraviolet for the excitation of 2PI. Phase and modulation measurements could be carried out at any integer multiple of the pulse repetition rate, up to our current limit of 10 GHz. The detector was an externally cross-correlated Hamamatsu R2566 MCP PMT.

The frequency-domain data consist of phase angle, φ_ω(λ), and modulation values, m_ω(λ), each measured for a particular wavelength, λ_{obs}, and for a range of modulation frequencies ω. These values are used to

obtain the best-fit parameters for the impulse response

\[ I(\lambda, t) = \sum_i x_i(\lambda) e^{-t/\tau_i}. \]  

(1)

By using this equation we assume that the decay times, \( \tau_i \), are constant across the emission spectrum. The values of the parameters \( x_i(\lambda) \) and \( \tau_i \) and the goodness-of-fit are determined from the minimum values of \( \chi^2_k \):

\[ \chi^2_k = \frac{1}{\nu} \sum \frac{(\Phi_{\text{obs}} - \Phi_{\text{cal}})^2}{\delta \Phi} + \frac{1}{\nu} \sum \frac{(m_{\text{obs}} - m_{\text{cal}})^2}{\delta m}, \]

(2)

where \( \nu \) is the number of degrees of freedom, and \( \delta \Phi \) and \( \delta m \) are the experimental uncertainties in phase and modulation values, respectively. The subscript \( c \) is used to indicate calculated values for assumed values of \( x_i \) and \( \tau_i \).

The fluorescence quantum yield \( \Phi_F \) was determined by comparison with that of a standard substance, quinine sulfate [12, 13], described in the previous papers [14, 15].

3. Results and Discussion

3.1. Decays of Monomer and Excimer Fluorescence

The mean lifetimes of 2PI in dilute p-xylene solution (10\(^{-5}\) M) is 1.87 ns. It is homogeneous and independent of the observation wavelength, \( \lambda_{\text{obs}} \), in the fluorescence band. The fluorescence spectrum of 2PI in p-xylene distinctly depends on the concentration (Figure 1). At high 2PI concentrations (above 10\(^{-3}\) M), a structureless excimer fluorescence band appears on the longwave side. In the case of the highest concentrations that could practically be achieved (7.8 x 10\(^{-2}\) M) for 2PI in p-xylene, two overlapping fluorescence bands, monomer and excimer, with comparable intensities at the emission maximum occur. The fluorescence decay of a concentrated solution (6 x 10\(^{-3}\) M) in p-xylene is heterogeneous and depends on \( \lambda_{\text{obs}} \). Therefore the decays were measured every 20 nm from 360 to 480 nm. The observation of the phase shift (Table 1) enables the conclusion to be drawn that the process dealt with occurs in the excited state when the final state (R) is pumped through the initially excited state (F). For a fixed modulation frequency (~200 MHz, Table 1) the fluorescence phase shifts at the longwave observation considerably exceed 90°, which clearly indicates that the observed fluorescence results from a process occurring in the excited state. Figure 2 shows schematically the decay runs for processes occurring in the excited state (e.g. excimers) in the time- and frequency-domain. The phase and modulation runs in a concentrated 2PI solution (6 \times 10^{-3} M) are shown in Fig. 3 for a short- (360 nm) and longwave (480 nm) observation. The wavelength dependence of the intensity decay in the fluorescence band of 2PI (c = 6 x 10\(^{-3}\) M) in p-xylene at 20°C is shown in Table 2. The intensity decay results obtained for each observation wavelength, \( \lambda_{\text{obs}} \), were fitted simultaneously with \( \tau_1 \) and \( \tau_2 \) as global parameters. \( \chi^2_k \) of this global fit is 3.9 (the uncertainties of phase and modulation measurements are \( \delta \Phi = 0.3^\circ \) and \( \delta m = 0.007 \), respectively).

The double exponential model, where \( \tau_1 \) and \( \tau_2 \) are common for all \( \lambda_{\text{obs}} \), was found to properly describe the fluorescence of 2PI. The single exponential model yields in this case (c = 6 x 10\(^{-3}\) M) a very poor fit (\( \chi^2_k = 1965 \)).

In the case of the shortwave observation, the monomer fluorescence is almost exclusively recorded.
whereas the share of the second component is small. The excimer state lifetime is relatively short: ~3.5 ns.

**3.2. Radiative and Non-radiative Rate Constants for Monomer Fluorescence**

The fluorescence quantum yield, \( \Phi_F \), given by the probability of a radiative transition divided by the total transition probability, is [16]

\[
\Phi_F = \frac{1}{\tau_e} \left( \frac{1}{\tau_e} + \frac{1}{\tau_1} \right)^{-1} = \frac{\tau}{\tau_e},
\]

where \( \tau_e \) and \( \tau_1 \) are reciprocals of the transition probability for radiation and for a non-radiative process, respectively. Thus, the natural radiative lifetime, \( \tau_e \), can be determined by measuring the lifetime \( \tau \) and the quantum yield \( \Phi_F \) of the fluorescence. The non-radiative lifetimes, \( \tau_1 \), can be calculated using the relationship

\[
\tau_1 = \frac{\tau}{1 - \Phi_F}.
\]

The quantum yield of 2PI measured in p-xylene is 0.27 (\( \lambda_{\text{exc}} = 318 \text{ nm} \)), which is markedly lower than that obtained in cyclohexane (according to Berlman [17], \( \Phi_F = 0.86 \)). Based on the values of \( \tau \) and \( \Phi_F \) for 2PI in p-xylene, \( \tau_e = 6.93 \text{ ns} \) and \( \tau_1 = 2.97 \text{ ns} \) were obtained for the monomer fluorescence.
2PI in p-xylene displays radioluminescence properties [8, 9]. It was shown, based on the Kallman and Furst theory [18, 19], that $\tau_e$ and $\tau_1$ can be determined using the following formulae involving the Kallman and Furst parameters, $P$ and $R$ [20]:

$$\tau_e = \frac{n_e \delta}{P/R} \tau,$$

$$\tau_1 = \frac{n_e \delta}{n_e \delta - P/R} \tau$$

($n_e$ denotes the number of electrons of the solvent excited per unit time, capable of transferring their energy to the solute, and $\delta$ is a constant parameter).

The following values were obtained for 2PI in p-xylene: $n_e \delta = 0.85$, $P = 0.05020$ mole/l, $R = 0.1528$ mole/l [9]. Thus, for the above values and the measured $\tau = 1.87$ ns, $\tau_e = 4.84$ ns and $\tau_1 = 3.07$ ns are obtained. A slight difference, in particular for the radiative lifetime, $\tau_e$, between the photoluminescence and radioluminescence results is probably due to the effect of the excimer fluorescence.
