From the knowledge of the spin correlation functions derived from Mössbauer relaxation spectra of quasi-one-dimensional $A_2$MnF$_3$(H$_2$O) with $A$ = Na, K or Rb and $A$ = Sr, Ba or $nH_2$, respectively [1–5]. In the light of this discussion, we will get back to previously reported studies of the $^{57}$Fe Mössbauer effect in the iron-doped compounds of $A_2$MnF$_3$(H$_2$O) and $A$MnF$_3$(H$_2$O) with $A$ = Na, NH$_4$, K or Rb and $A$ = Sr, Ba or $nH_2$, respectively [6–12], where we investigated the spin-dynamics and non-linear excitations (solitons) in these compounds. From the analysis of Mössbauer relaxation spectra based on the classical soliton model [13–18] we were able to determine the activation energy for such a soliton from the temperature dependence of the spin-fluctuation rate in the antiferromagnetic 1-d phase even of powder samples [8–10, 12, 19–21].

Structural Properties of $A_2^1$/$A^1$MnF$_3$(H$_2$O)

The Jahn-Teller theorem is applicable to the degenerate ground state of manganese(III) complexes with octahedral symmetry. In case of Mn$^{3+}$ (3d$^4$) with $S$ = 2, the 3D$_2$ term is split in an octahedral field to yield a 2E$_g$ ground state and a 4T$_2g$ excited state [22, 23]. If the octahedral symmetry of the ligand field is reduced by the Jahn-Teller effect to axial symmetry, the octahedra are remarkably lengthened in the bridging direction, the orbital degeneracy of the 2E$_g$ ground state is removed. If the $x$ and $y$ axes point at the in-plane fluorine ligands, the d-orbitals will be arranged such that $d_{xz}$ and $d_{yz}$ remain degenerate, followed by $d_{z^2}$ and lastly by $d_{x^2-y^2}$ as the most destabilized antibonding orbital. For a compressed octahedral arrangement the $d_{x^2-y^2}$ orbital is stabilized. In this scheme the four 3d-electrons will generate a $^4$Bi$_{1g}$ or $^2$A$_{1g}$ ground state for axially elongated or compressed octahedra, respectively [11].

When mixing of the ground and excited states becomes important, the susceptibilities differ from the spin-only prediction and become anisotropic due to the existence of a local anisotropy (zero-field splitting) [8].

A common feature of all fluoromanganates(III) with the general formula $A_2^1$/$A^1$MnF$_3$(H$_2$O) is that they are built from infinite chains of trans corner-linked [MnF$_4$F$_2$]$_2^{2-}$ octahedra, with individual chains being separated by alkaline ($A^+$) or earth alkaline ($A^{2+}$) ions [11]. In our case of $A_2$MnF$_3$(H$_2$O) these counter-ions are Na$, (NH_4)^+$, K$^+$, and Rb$^*$. Due to the Jahn-Teller effect, the long axial Mn–F$_{a}$ bonds of the distorted [MnF$_4$F$_2$]$_2^{2-}$ octahedra all lie along the chain direction, which yields a ferrodistortive [32] arrangement. An increase in size of the counter-ion results in a widening of the (Mn–F$_{a}$–Mn) bridging angle $\gamma$ from 132.5$^\circ$ for Na$_2$MnF$_4$ to 175.4$^\circ$ for Rb$_2$MnF$_4$(H$_2$O) (see Table 1) [3]. The coordination around Mn(III) is very nearly axially symmetric (D$_{4h}$). The EPR-spectra for a single crystal of...
Table 1. Structural data in the following order: Mn-F-Mn bridge angle $\gamma$, Mn-Mn intrachain distance, Mn'-Mn interchain distance, Mn-F terminal bond $M_{eq}$, the Mn-F bridge bond $M_{ax}$, and the space group SG.

$(\text{NH}_4)_2\text{MnF}_5$ (space group Pnma, $Z=4$) were found to be nearly isotropic with signals at $g$ values of $g_\perp=2.002$ and $g_\parallel=1.997$ [33].

For orthorhombic symmetry, the influence of zero-field splitting on the measurable magnetic properties can be accounted for by addition of two terms to the isotropic exchange interaction. The Hamiltonian for the single chain in a magnetic field may be written in the form

$$
\hat{\mathcal{H}} = \sum (-2 J S_i S_{i+1} + D \left( S_{z,z}^2 - \frac{1}{3} S_i(S_i+1) \right) + E (S_{x,x}^2 - S_{y,y}^2) - g \mu_B H S_i),
$$

where $S$ and $S_i$ ($=x, y, z$) are spin operators related to the actually occupied energy levels. The chain direction is along the $z$ axis. The first term in (1) represents an isotropic Heisenberg exchange interaction between two neighbouring spins in the chain. $D$ and $E$ are the axial and orthorhombic crystal field parameters. The single-ion type anisotropy may arise from the crystal potential. Since the equatorial Mn-F$_{eq}$ distances in the plane perpendicular to the $z$ axis differ only by less than 0.1% we will neglect the orthorhombic anisotropy $E$ (third term in (1)) in our discussion. The fourth term in (1) represents the Zeeman-interaction.

As has previously been shown for Mn(III) chain compounds of the type $A^I_2/A^{II}_4\text{MnF}_5(\text{H}_2\text{O})$ [21], it follows that $|D| \gg E$ and $|J| > |D|$. The model given in (1) is therefore a valid approximation to describe the properties of a 1-d Mn$^{3+}$ magnetic system.

**Correlation Length**

In previous papers [6–12, 19–21] we demonstrated that Mössbauer spectroscopy is a suitable method to study non-linear excitations in one-dimensional antiferromagnetic chain compounds of $A^I_2\text{Mn}(\text{III})_{0.98}\text{Fe}(\text{III})_{0.02} \text{F}_5(\text{H}_2\text{O})$ and $A^{II}_4\text{Mn}(\text{III})_{0.98}\text{Fe}(\text{III})_{0.02} \text{F}_5(\text{H}_2\text{O})$.

The characteristic Mössbauer parameters as quadrupole splitting and magnetic hyperfine field $H$ are listed in Table 2 or are given in [6–12, 19–21]. The detailed theoretical analysis of domain wall dynamics and solitons in magnetic chains with a large local anisotropy $D$ shows that, in a certain range above the critical temperature $T_N$, the density of $\pi$ domain walls and their motion determines the spin autocorrelation function $(S(0)S(t))$, which is obtained by measuring the fluctuating hyperfine field $H(t) \propto S(t)$. The temperature dependence of the Mössbauer spectra for a representative powder sample of $(\text{NH}_4)_2\text{Mn}(\text{III})_{0.98}\text{Fe}(\text{III})_{0.02} \text{F}_5$ (one of ten investigated fluoromanganates(III) compounds) is shown in Figure 1. The Mössbauer spectra could successfully be fitted, as for all other compounds, by adopting the Blume Tjon relaxation model [34–36], in which it is assumed that the hyperfine field jumps stochastically with a flipping rate $\Gamma$ between the two possible value $+H_H$ and $-H_H$. This takes into account a time-dependent Hamiltonian [36]. Thus, the hf interaction is replaced by a fluctuating effective field, and the increase in the fluctuation rate causes line broadening, asymmetric spectra, and related phenomena [16]. In doing so, the Mössbauer spectra could be fully fitted at all temperatures, with the spin fluctuation rate $\Gamma$ and the ratio of the probabilities that $+H_H$ jumps to $-H_H$ and vice versa, as the only adjustable, temperature-dependent parameters.
Table 2. Experimentally determined parameters in the following order: complementary angle \( \delta \) by X-ray diffraction [3], static Mössbauer parameters of the magnetic hyperfine field \( H_{hf} \), the quadrupole splitting \( \Delta E^Q \) at 4.2 K, and the calculated thermal activation energy \( E_A/k \) from the relaxation spectra on the basis of the classical soliton theory. Parameters obtained by measurements on powders and single crystals for the 1-d antiferromagnetic intrachain exchange constant \( J \) and the soliton energy \( E_s \), the anisotropy constant \( D \), the Neél temperature \( T_N \), the interchain exchange constant \( J' \), the ratio \( J'/J \) and the canting angle \( \phi \) derived from (15), respectively. The anisotropy constants in Table 2 are to compare with the averaged value \( D/k = 2.75(3) \) K derived from Mössbauer spectroscopy (see Figure 3).

*) Powder sample.

Based on the classical soliton theory [16, 37–45] we discussed and analyzed the spin fluctuation rates \( \Gamma \) for NaMn\(_{0.98}\)Fe\(_{0.02}\)F\(_5\) [12]. (NH\(_4\))\(_2\)Mn\(_{0.98}\)Fe\(_{0.02}\)F\(_5\) [9], enH\(_2\)Mn\(_{0.98}\)Fe\(_{0.02}\)F\(_5\) [10], K\(_2\)Mn\(_{0.98}\)Fe\(_{0.02}\)F\(_5\)(H\(_2\)O), and Rb\(_2\)Mn\(_{0.98}\)Fe\(_{0.02}\)F\(_5\)(H\(_2\)O) [8]. We want to emphasize that a feature of our experimental results is the observation of two subspectra, each of which shows a separate relaxation mechanism. Approaching the magnetically split phase from above one observes the apparent coexistence of contributions from the paramagnetic and magnetically ordered phase. This transition is accompanied by slow and fast relaxation phenomena, which may be attributed to non-linear excitations of domain walls. This unusual behaviour is observed in (NH\(_4\))\(_2\)Mn\(_{0.98}\)Fe\(_{0.02}\)F\(_5\) between 9 and 13 K (Figure 1). There appears a central asymmetric doublet due to faster relaxation. Above 13 K, the intensity of the slowly relaxing subspectrum becomes negligible, such that only a single spectrum is sufficient to fit the experiment. These features were in common for all our samples studied by Mössbauer spectroscopy and were also observed by de Jongh and his group [16–18]. The Mössbauer spectra were assumed to consist of two subspectra with equal static parameters but different relaxation rates.

To obtain the fliprate \( \Gamma \) from the measured spectra we have employed, as mentioned above, the Blume and Tjon model. The spin fluctuation rate \( \Gamma \) is defined as (see for example de Groot [16])

\[
\Gamma = 2 n_s v_s = v_s \xi^{-1},
\]

where \( n_s \) is the soliton density,

\[
n_s = \frac{8}{\pi} \frac{\left| J \right|}{d} \frac{E_s}{kT} \exp \left( -\frac{E_s}{kT} \right),
\]

\( v_s \) the soliton velocity:

\[
v_s = \frac{4 \left| J \right| S^2}{E_s \sqrt{2kT}},
\]

d the width of a domain wall:

\[
d = \frac{4 \left| J \right| S^2}{E_s} = \frac{\sqrt{J}}{\sqrt{\left| D \right|}},
\]

and \( E_s \) is the soliton energy:

\[
E_s = 4 S^2 \sqrt{\left| D \cdot J \right|}.
\]

For the inverse correlation length \( \xi^{-1} \) (see (2)) it follows that

\[
\xi^{-1} = 2 n_s \sqrt{\frac{8}{\pi} \frac{\left| J \right|}{d} \frac{E_s}{kT} \exp \left( -\frac{E_s}{kT} \right)},
\]

(7a)

Therefore the spin fluctuation rate \( \Gamma \) derived from the Mössbauer spectra can be expressed by

\[
\Gamma = 2 n_s v_s = \frac{8}{\pi} \frac{\left| J \right| S}{\sqrt{D \cdot J}} \exp \left[ -\frac{E_A}{kT} \right].
\]
In our earlier papers it has been shown that this spin fluctuation rate, resulting from non-linear excitations, appears both in ferro- and antiferromagnetic Ising-like chain systems at temperatures roughly between \( T_c \) and \( 3T_c \), where \( T_c \) is the three-dimensional ordering temperature. The activation energy \( E_A \), as determined from the electronic fliprate as a function of inverse temperature (see (8)), was systematically found to be twice the energy \( E_s \) of a single soliton, that is it corresponds to the energy of a soliton pair [46, 47]. This result is in contrast to the ideal gas description predicting the activation energy to be that of a single soliton. In the ideal soliton approximation [48] it is supposed that the solitons are present on the basis of entropy considerations, and their displacement is responsible for the spin fluctuations. Since the soliton pair excitations appear to be thermally activated, it is most probable that the coupling between the phonon bath and the spin system is responsible for their creation and annihilation. The present chain systems show spin-orbit coupling, which may provide for the thermal link between the phonon and the spin system [49].

Fig. 1. Representative Mössbauer spectra for \((\text{NH}_4)_2\text{Mn}_{0.98}\text{Fe}_{0.02}\text{F}_5\). The continuous line represents a least-squares fit to the applied relaxation model of Blume and Tjon [34–36].
The second subspectrum, a asymmetric doublet relaxes fast and shows a temperature independent relaxation rate. We had identified this subspectrum with the intra-band excitations discussed by Nagler et al. [50]. The level splittings in this soliton pair band are small with respect to the temperature, resulting in a fast relaxation behaviour. We remark that these rapid fluctuations have to be restricted to only parts of the chain during the characteristic Mössbauer time, since otherwise the slowly relaxing component would simply be not present. It is worthwhile to comment that the fast relaxing doublet disappears if a magnetic field is applied. This is expected, since an applied field polarizes the spins and lifts the degeneracy of their energy levels.

In Fig. 2 we present the relaxation rate versus inverse temperature for the $^{57}$Fe doped compounds of the fluoromanganates(III) mentioned above. Additionally, we present the unpublished measurements for SrMnF$_5$(H$_2$O), BaMnF$_5$(H$_2$O) in Fig. 2 [21]. The slopes for the exponentials are $2E_s$. It follows from the plots of $\ln(\Gamma)$ vs. $1/T$ that the soliton energy $E_s$ may be determined directly from Figure 2. The derived activations $E_s/k$ are listed in Table 2.

The results obtained by the classical soliton theory (see (2)–(8)) are only strictly valid in the low temperature region ($T \to 0$) [16], since it requires the solitons not to interact (see above). The application of (7a) for higher temperatures (higher soliton density) is therefore rather questionable. For higher temperatures a boundary condition is, that the inverse correlation length $\xi^{-1}(T)$ for $T \to |J| S(S+1)/k$ turns continuously to an isotropic be-

![Fig. 2. Relaxation rate (fliprate) versus inverse temperature for Na$_2$Mn$_{0.98}$Fe$_{0.02}$F$_5$, (NH$_4$)$_2$Mn$_{0.98}$Fe$_{0.02}$F$_5$, SrMn$_{0.98}$Fe$_2$O$_{2.02}$F$_5$(H$_2$O), enH$_2$Mn$_{0.98}$Fe$_{0.02}$F$_5$, K$_2$Mn$_{0.98}$Fe$_2$O$_{2.02}$F$_5$(H$_2$O), and Rb$_2$Mn$_{0.98}$Fe$_2$O$_{2.02}$F$_5$(H$_2$O). The slopes of the exponentials were calculated by a least squares fit. Their values represent the activation energies which are to be compared with the soliton energy $E_s$.](image)

![Fig. 3. The relationship between the activation energy $E_A=(2E_s)^2$ and the antiferromagnetic 1-d exchange constant $|J|$. From a linear least squares fit we derive from the classical soliton model $E_s=4S^2(|J|)^2$ the local anisotropy energy $|D/k|=2.75(3)$ K.](image)
Fig. 4. Magnetic susceptibility in the three crystallographic axes vs. temperature for \( \text{Rb}_2\text{MnF}_5(\text{H}_2\text{O}) \). The solid lines are calculated by the model given in the text with the parameters of the anisotropy constant \( D/k = -2.95(3)\, \text{K} \), the exchange constant \( J/k = -20.1(3)\, \text{K} \), the Néel temperature \( T_N = 22.8(5)\, \text{K} \), the spin canting angle \( \phi \equiv 0.0(5)^\circ \), and the soliton energy \( E_s/k = 117(3)\, \text{K} \). The solid line of \( \chi_H \) represents the solution for the isotropic Heisenberg model.

 behaviour predicted by the Heisenberg model \([51, 52]\) and given by:

\[
\xi^{-1} = -\ln \left[ \coth \left( \frac{2|J|S(S+1)}{kT} \right) - \frac{kT}{2|J|S(S+1)} \right]. \tag{7b}
\]

From this simple model of isotropic spin interactions we had calculated the exchange constants near \( T(\chi_{\text{max}}) \) many years ago \([3]\). Figure 3 shows now the correlation between the activation energy \( (2E_s)^2 \) derived from the classical soliton model and the antiferromagnetic 1-d exchange constants \( J \) (see Table 2). From a linear least squares fit (Fig. 3) we derive the local anisotropy energy \( |D/k| = 2.75(3)\, \text{K} \).

We can test the predictions of the soliton theory (see \((2)\)-(8)) by calculating the magnetic susceptibilities from the temperature dependence of the inverse correlation length \( \xi^{-1}(T) \) and compare these with experimental results obtained from magnetic measurements on single crystals of the fluoromanganates(III).

Magnetic Susceptibility along the Chain-direction

In Figs. 4, 5, and 6 we present the magnetic susceptibilities as examples for single crystals of \( \text{Na}_2\text{MnF}_5 \), \( \text{(NH}_4\text{)}_2\text{MnF}_5 \), and \( \text{Rb}_2\text{MnF}_5(\text{H}_2\text{O}) \). Previously \([9]\) we reported magnetic investigations on single crystals of \( \text{(NH}_4\text{)}_2\text{MnF}_5 \), \( \text{(NH}_4\text{)}_2\text{MnO}_{0.08}\text{Fe}_{0.02}\text{F}_5 \), and \( \text{enH}_2\text{MnF}_5 \) \([10]\). The magnetic studies on single crystals of \( \text{Na}_2\text{MnF}_5 \) (15 mg), \( \text{(NH}_4\text{)}_2\text{MnF}_5 \) (40 mg), \( \text{enH}_2\text{MnF}_5 \) (12 mg), \( \text{K}_2\text{MnF}_5(\text{H}_2\text{O}) \) (11 mg), and \( \text{Rb}_2\text{MnF}_5(\text{H}_2\text{O}) \) (20 mg) were performed with a SQUID magnetometer \([53]\) in the temperature range 1.7–330 K and external fields up to ±55 kG. The experimental procedure for determining the Néel temperatures has been described in detail in \([12]\). These transition temperatures \( T_N \) are listed in Table 2.

The experimental \( \chi(T) \) data for \( \text{Na}_2\text{MnF}_5 \), \( \text{(NH}_4\text{)}_2\text{MnF}_5 \), and \( \text{Rb}_2\text{MnF}_5(\text{H}_2\text{O}) \) represent the susceptibilities along the chain directions \( a \), \( b \), and \( c \), and \( \chi_{\perp}(T) \) are the perpendicular susceptibilities along the \( b \) and \( c \) or \( a \) and \( c \) or \( a \) and \( b \) axes, respectively. In the 3-d ordered magnetic phase the hierarchy of the \( \chi_{\perp} \) components is for example as follows: \( \chi_b > \chi_c \) for \( \text{Na}_2\text{MnF}_5 \), \( \chi_a > \chi_c \) for \( \text{(NH}_4\text{)}_2\text{MnF}_5 \), and \( \chi_a > \chi_b \) for \( \text{Rb}_2\text{MnF}_5(\text{H}_2\text{O}) \).

If the temperature dependence of the correlation length is known (see \((7a)\)), the static pair-correlation function for the compounds in question may be determined. According to Fisher \([51, 54]\) the correlation function is given as

\[
C_r(T) = \langle S^r_0 S^r_\infty \rangle = \frac{S(S+1)}{3} \cdot \exp(-\xi^{-1}), \quad \tag{9}
\]

\( (r = 0, 1, 2, \ldots, \infty) \).
Fig. 5. Single crystal magnetic susceptibility of (NH$_4$)$_2$MnF$_5$ for the three crystallographic axes vs. temperature. The curves are calculated from the present model. The obtained parameters are the anisotropy constant $D/k = -2.85(3)$ K, the exchange constant $J/k = -10.6(1)$ K, the Néel temperature $T_N = 8.5(2)$ K, the spin canting angle $\varphi = 4.6(2)^\circ$, and the soliton energy $E_s/k = 83(2)$ K. The solid line of $\chi_H$ represents the solution for the isotropic Heisenberg model.

Fig. 6. Single crystal magnetic susceptibility of Na$_2$MnF$_5$ for the three crystallographic axes vs. temperature. The solid lines are calculated with the parameters of the anisotropy constant $D/k = -2.85(4)$ K, the exchange constant $J/k = -8.8(2)$ K, the Néel temperature $T_N = 9.2(2)$ K, the spin canting angle $\varphi = 5(1)^\circ$, and the soliton energy $E_s = 70(3)$ K. The solid line $\chi_H$ represents the solution for the isotropic Heisenberg model.
where (8) describes the degree of correlation between a reference spin $S_0$ and a varying (fluctuating) spin $S_r$ at the distance $r$.

According to Steiner et al. [42] the susceptibility of a 1-d antiferromagnet follows

$$X_{\parallel}(T) = \frac{N g^2 \mu_B^2 S(S+1)}{3kT} \cdot \frac{1 - \exp \left( - \frac{b_0}{\xi} \right)}{1 + \exp \left( - \frac{b_0}{\xi} \right)}.$$

For $\xi \to 0$ and $T \to JS(S+1)/k = T(\chi_{\text{max}})$, $X_{\parallel}$ smoothly approaches the Curie law. The term $(S(S+1)/3) \cdot \exp(-1/\xi)$ represents the correlation function $\langle S^z_0 S^z_r \rangle$ of (9). $b_0$ is the shortest metal–metal distance along the chain direction. According to (7a) we find the relation

$$\exp \left( - \frac{b_0}{\xi} \right) = \exp \left( -2b_0 \sqrt{\frac{8}{\pi}} \sqrt{\frac{D}{J}} \sqrt{\frac{E_s}{kT}} \cdot \exp \left( - \frac{E_s}{kT} \right) \right).$$

If we insert this expression, derived from the soliton model (see (7a)), in (10), the calculation yields the parallel component of the magnetic susceptibility, which is represented by a solid line in Figs. 4–6 and has been labeled $X_{\parallel}$. For Na$_2$MnF$_5$ the simulation of the magnetic susceptibility $X_{\parallel}$ by (9) is excellent. For (NH$_4$)$_2$MnF$_5$ the theoretical values according to (10) come close to the maximum of the magnetic susceptibility at $T = T(\chi_{\text{max}}) = S(S+1)|J|/k = 63 K$. For Rb$_2$MnF$_5$(H$_2$O) with $T(\chi_{\text{max}}) = 128 K$ the correlation function used in (10) breaks down for temperatures higher than 60 K.

For comparison we have also plotted the results for the magnetic susceptibility $X_{\text{H}}$ according to the Heisenberg-model (see (7b)) in Figs. 4, 5, and 6. It is valid for $T > T(\chi_{\text{max}})$ since the effective spin-correlations along the chain vanish at $T(\chi_{\text{max}})$. The correlation length $\xi$ for temperatures $T = JS(S+1)/k$ is smaller than the average intermetallic Mn$^{3+}$–Mn$^{3+}$ distance of 4 Å. This is demonstrated in Fig. 7 for the compounds of (NH$_4$)$_2$MnF$_5$ and Rb$_2$MnF$_5$(H$_2$O), where the calculated correlation lengths of the classical soliton model (7a) are plotted as functions of temperature $T$. The parameters $D$, $J$, and $E_s$ found from the least squares fit are given in Table 2. As starting parameters we used $D$ and $E_s$ derived from our Mössbauer relaxation spectra.
Additionally, we have recalculated the correlation lengths from (9) using the relation

$$\xi^{-1} = \ln \left( \frac{1 - A}{1 + A} \right) \quad \text{with} \quad A = \frac{3 X_\parallel kT}{N g^2 \mu_B S(S+1)}.$$  

Inserting in (12) the measured values $X_\parallel$, we obtain the temperature dependence of $\xi^{-1}$ derived from the magnetic susceptibility. These calculated values were inserted in Fig. 8 as points. The comparison confirms that the analytical form $\xi^{-1}(T)$ derived from the spin dynamics is not very different and describes $\chi_\parallel$ nicely, at least in the low temperature region (Figure 8). For large temperatures $T \to T(\chi_{\max})$ the analytical form of (7a) failed, especially for compounds with large $T(\chi_{\max})$ values.

Figures 4, 5, and 6 demonstrate that the correlation lengths determined on the basis of the soliton model describe the parallel component of the magnetic susceptibility correctly for temperatures below 60 K.

For higher temperatures ($T \geq 60$ K) where the wall separation is comparable to the wall width, that is $\xi = b_0$, one has to take interactions between the solitons as well as simultaneous excitations of solitons and antisolitons (excited pair-states) into account [16, 18, 46, 47]. In this temperature regime, the soliton velocity $v_s$ is possibly slowed down due to the soliton–antisoliton and soliton–phonon interactions [16]. This demonstrates that at higher temperatures the classical soliton model breaks down. It is worth noting that for high temperatures within the 1-d phase the quality of fitting can be increased by assuming that the soliton velocity is nearly temperature independent.

A series expansion in powers of $(kT/E_s)$ after Sasaki and Tsuzuki [55], which accounts for the existence of a magnon as well as a soliton contribution, does not improve the description of the temperature dependence of correlation lengths $\xi_{\parallel}$ or $\chi_\parallel$ in the high temperature region.

Griffiths [56] has suggested a perturbation procedure by which a semiquantitative description to the axial anisotropy might be built upon Fisher’s classical Heisenberg model [51]. From his evaluation of the higher-order spin-correlation functions Smith et al. [52] and Kida et al. [26] derived for $\chi_\parallel$ and $\chi_\perp$ an analytical expression. This expression, however, is in contradiction to our results and to the requirement of an exponential increase in the correlation length $\xi_\parallel$ if one approaches absolute zero, or that for $T \to 0$ the static correlation function should approach unity. The perturbation procedure by Griffiths is expected to be valid only where the anisotropy $\chi_\perp - \chi_\parallel$ is not large compared to the average susceptibility $(\chi_\parallel + 2\chi_\perp)/3$, i.e. in a certain region below $T(\chi_{\max})$ within the 1-d antiferromagnetic phase.

Since the pure 1-d antiferromagnet has no finite $T_N$, irrespective of the symmetry of the Hamiltonian, the observed transition is due to the weak interchain coupling $J'$. Nevertheless, the value of $T_N$ is directly related to the 1-d correlation length $\xi_{\parallel}(T)$ along the chain, as follows from the relation

$$kT_N \equiv |J'| S(S+1) \cdot \xi_{\parallel}(T_N),$$  

which equates the thermal energy at $T_N$ to the interaction energy between correlated chain segments on adjacent chains [45]. Because the Néel-temperatures $T_N$ of 8.5(2) and 22.5(3) K and the 1-d correlation lengths $\xi_{1D}(T_N)$ are known from (7a), the inter-chain exchange energies $|J'/k|$ for (NH$_4$)$_2$MnF$_4$ and Rb$_2$MnF$_4$(H$_2$O) result to $2.7(3) \cdot 10^{-4}$ K and $1.6(3) \cdot 10^{-5}$ K, respectively. The ratio $|J'/|J| = R$, which is a measure for the one-dimensionality of a magnet, results to $2.6 \cdot 10^{-5}$ (NH$_4$) and $8.3 \cdot 10^{-4}$ (Rb).

In Table 2 we placed together the local anisotropy $D$, 1-d exchange constant $J$, soliton energy $E_s$, inter-chain exchange constant $J'$, and Néel-temperature $T_N$ derived from our calculations.
Fig. 9. Fitting of the magnetic susceptibility of the powder sample of (NH4)2MnF5 with the relation (15) described in the text. As starting parameters the anisotropy constant and the Néel temperature were fixed and the susceptibility was varied as a function of J and \( \phi \). Finally, the susceptibility was calculated with the parameters of the anisotropy constant \( D/k=2.85(5) \) K, the exchange constant \( J/k=10.4(2) \) K, the soliton energy \( E_s/k=85(2) \) K, the spin canting angle \( \phi=4.6^\circ \), and the Néel temperature \( T_N=8.5(1) \) K.

Magnetic Susceptibility Perpendicular to the Chain-direction

From our single crystal measurements we find, as mentioned above, that the spins are nearly antiparallel to the z axis (chain direction), but they have small canted components along the x or y axes (perpendicular to the chain direction) in the ordered state, which produce a weak ferromagnetism. Previously, magnetic measurements on a single crystal of (NH4)2MnF5 with the transverse detection unit of our SQUID system [53] showed that the ferromagnetic moment lies within the a, c plane for \( T<T_N \) [21]. The canting angle \( \phi \) is caused by the local anisotropy producing a different preferential direction for the moment which are on different sublattices. This mechanism occurs when the local arrangement of the atoms around the sites of the magnetic ions are tilted with respect to each other.

The direction of local anisotropy for each sublattice is assumed to make an angle \( \delta=(180^\circ-\gamma)/2 \) with the positive or negative z axis, where \( \gamma \) represents the bridging angle (Table 1). If the preferred direction due to the anisotropy is the same for both sublattices (\( \delta=0 \)), the canting angle \( \phi \) is evidently equal to zero. An increase of \( \delta \) also increases the canting angle. If, on the other hand, the exchange interaction \( J \) is zero, it is easily seen that \( \delta=\phi \).

To describe the spin behaviour one has, as mentioned above, to solve the Hamiltonian of a magnetic chain for orthorhombic symmetry. Due to the isotropy within the plane perpendicular to the chain axis (\( E\equiv0 \)) we can construct the following expression for the susceptibility perpendicular to the chain axis. According to Moriya [57] the magnetic susceptibility of a canted system may be described by the sum of two contributions, namely an antiferromagnetic and a ferromagnetic part. Each of the contributions must be multiplied with an appropriate factor to take the value of the susceptibility component along the particular axis into account. For our description of the experimental susceptibility data on the weak ferromagnetic chain compounds, we used the correct theoretical expression for the 1-d Heisenberg model, multiplied with the factor \( 1/\sin^2\phi \) [57]. Following Moriya [57], the ferromagnetic component can be described by a term \( C/(T-T_N) \) multiplied with the factor \( \sin^2\phi \), where \( C \) is the Curie constant. In our case, for \( \chi_L \) it follows that

\[
\chi_L = \frac{N g^2 \mu_B^2}{3kT} \frac{S(S+1)(1-\sin^2\phi)}{1+\exp(\frac{\xi_H^{-1}}{kT})} \left[ 1 + \exp(\frac{\xi_H^{-1}}{kT}) \right]
\]

\[
+\frac{N g^2 \mu_B^2}{3k(T-T_N)} \sin^2\phi \cdot \left( 1 - \exp(\frac{\xi_H^{-1}}{kT}) \right) \left[ 1 + \exp(\frac{\xi_H^{-1}}{kT}) \right] \]

where \( \xi_H^{-1} \) represents the inverse correlation length (see (9)) in the Heisenberg model. The Figs. 4, 5, and 6 show the results for best fits of (14) to the experimental data for the perpendicular component of the magnetic susceptibility \( \chi_L \). For Na2MnF5, (NH4)2MnF5 and Rb2MnF5(H2O) values of \( T_N=9.5 \) K, 8.5 K or 22.5 K and \( \phi=5.1^\circ, 4.8^\circ \) or \( 0.4^\circ \) have been taken into account.

Considering (10) and (14), we can derive an expression calculating the magnetic susceptibilities of powder samples as is demonstrated for the case of (NH4)2MnF5 in Figure 9. The average magnetic susceptibility may then be written as

\[
\chi_{\text{Powder}} = \frac{1}{3} \left( \chi_\parallel + 2 \cdot \chi_L \right)
\]

(15)

\[
= \frac{N g^2 \mu_B^2}{3k} \frac{S(S+1)}{3} \left( \frac{1}{T} - \frac{1 - \exp(\xi_H^{-1})}{1 + \exp(\xi_H^{-1})} \right)
\]

\[
+ \left[ \frac{2}{T} \left( 1 - \sin^2\phi \right) \frac{1 - \exp(\xi_H^{-1})}{1 + \exp(\xi_H^{-1})} + \frac{\sin^2\phi}{T - T_N} \right] \cdot \left( \frac{1}{3} - \frac{1 - \exp(\xi_H^{-1})}{1 + \exp(\xi_H^{-1})} \right) \right].
\]
Fixing as starting parameters the Néel temperature $T_N$ and the exchange constant $J$, the adjustable parameters are the anisotropy constant $D$, the soliton energy $E_s$, and the spin canting angle $\varphi$. Finally we found from the best fit of (15) to the data: of $(\text{NH}_4)_2\text{MnF}_5$: $D/k = -2.85(5) \text{ K}$, $J/k = -10.4(2) \text{ K}$, $E_s = 85(3) \text{ K}$, and $\varphi = 4.5^\circ$ (see Figure 9). These results are in excellent agreement with our single crystal study.

In order to check our results discussed above we have started to perform inelastic neutron scattering experiments at the Hahn-Meitner-Institute at BER-II in Berlin to determine the magnetic linear [28] and non-linear excitations of $(\text{NH}_4)_2\text{MnF}_5$. However, the inelastic magnetic signals were weak and strongly hidden by the large incoherent background caused by the hydrogen atoms.

After the availability of large deuterated single crystals (1.5 g) of good quality, which have been characterized crystallographically by elastic neutron diffraction [27], the study of inelastic neutron scattering has been performed on the compound $(\text{ND}_4)_2\text{MnF}_5$. The results, which will be published elsewhere [58], are in excellent agreement with our investigations above.
