ESR, Cu(II) Complexes, Synthetic Zeolites

The ESR spectroscopy is used for the study of the motion of Cu(en)2+ and Cu(tmen)(OH)2 in fully hydrated X and Y zeolites. At room temperature steric hindrance in the faujasite cavities and slow motion condition lead to partially anisotropic spectra.

In frozen samples, calculation of bonding coefficients indicate small interaction with surface walls.

The electron spin resonance (ESR) line shape has been recently investigated in our laboratory in order to study the mobility of transition metal ions dissolved in water adsorbed on porous supports1-3.

Hydrated metal ions after adsorption on porous solids generally give rise to liquid-type ESR spectra in the motional narrowing region which allow to infer relevant information on the properties of water in highly disordered porous systems2 or in the almost regular crystal lattices of synthetic zeolites3.

Vacuum heating leads to migration of the metal ion into specific sites of the bulk of the solids or into different cavities of zeolites4. A lot of papers has been devoted, for instance, to the migration and localization of Cu2+ ions in the different sites of the zeolite cavities after vacuum heating5-10. The electron spin relaxation of Cu(H2O)62+ in the temperature region of fast motion after adsorption into hydrated zeolites has also been investigated3.

In this work we focus our attention on the motion and localization of large complexes of Cu(II) adsorbed in the faujasite cavities of fully hydrated X and Y zeolites and a comparison with the behaviour of Cu(H2O)62+ is made. Semiquantitative evaluation of the bonding coefficients is carried out in order to study the interaction between adsorbed complexes and the zeolite framework.

Experimental

Na Linde X and Y zeolites were exchanged following the usual method by using 0.02 M aqueous solution of the appropriate copper complexes. Cu(H2O)62+ was introduced from a copper nitrate solution. Copper complexes with H2N-CH2-CH2-NH2 (en) and (CH3)2N-CH2-CH2-N(CH3)2 (tmen) have been prepared by adding the purified ligand to aqueous solution of copper nitrate up to Cu/ligand ratio 1:20. Exchange has been carried out from these solutions. The powdered exchanged zeolites were stored in a water-vapour-saturated box in order to maintain fully hydrated samples. ESR spectra were registered with a Varian V 4502 spectrometer (X-band) equipped with conventional assembly for temperature variation. Linewidth, g-factor and hfs coupling constant measurements were made by comparison with potassium nitrosodisulphonate (g = 2.0054, ax = 13.0 G).

Results and Discussion

Both X and Y fully hydrated zeolites, after exchange with Cu(H2O)62+ water solution, show an almost symmetrical ESR signal centered at g = 2.18 and linewidth ~ 150 G, as previously observed by NICULA et al.5 and by NACCACHE and BEN TAARIT6. The temperature dependence in the region of motional narrowing indicates free rotation of this species in the faujasite cavity3,4. From the analysis of the linewidth the correlation time for the re-orientation of the complex and for the rapid jump of the Jahn-Teller distortion axis have been previously evaluated3.

By freezing out, a complex ESR pattern is obtained (Fig. 1). It indicates the presence of two species characterized by different ESR parameters summarized in the Table I. The first one, which is much more intense, has almost the same parameters as obtained in frozen water solution of Cu(H2O)62+ and it is clearly due to hydrated Cu(II)

</table>

\(^a\) Isotropic values of \(g\) and \(A\) are evaluated from room temperature spectra.

When adsorbed on synthetic X and Y zeolites, they can only enter in the faujasite cavity. The observed spectra are, however, anisotropic even at room temperature with poorly averaged anisotropies of \(g\) and \(A\) whose values are similar to those in frozen samples (Fig. 3 and Table I). This fact indicates that in the faujasite cavities of X and Y zeolites the large copper complexes, as contrasted with hydrated ions, have very low mobility, with tumbling rate sufficiently slow to prevent averaging of the anisotropies. Similar results have been reported for vanadyl complexes adsorbed on zeolites\textsuperscript{14}. Slow

trapped in the water filling the supercavity. The second signal can be attributed to copper ions localized on the walls of the cavity (presumably on the \(S_{11}\) sites\textsuperscript{6}).

Copper complexes with ethylenediamine (en) and with \(N,N,N',N'\)-tetramethylethylenediamine (tmen) in water solution at our experimental conditions are predominantly Cu(en)\textsubscript{3}\textsuperscript{2+} and Cu(tmen)(OH)\textsubscript{2}\textsuperscript{12,13}. At room temperature the complexes give rise to isotropic spectra with well resolved four hpf lines (Fig. 2). The ESR parameters at room and liquid nitrogen temperature are reported in the Table I.
motion conditions, which are expected for \( \tau_r \) in the range \( 10^{-8} - 10^{-10} \) sec \(^{15-17} \) may be responsible of the observed effects. Indeed, for \( \text{Cu(H}_2\text{O)}_6^{2+} \) in fully hydrated zeolites was found \( \tau_r = 3.6 \times 10^{-10} \) at 25 °C \(^3\) and somewhat larger values should be expected for \( \text{Cu(en)}_2^{2+} \) and \( \text{Cu(tmen)}(\text{OH})_2 \). In our opinion the major reason of the anisotropy resides, however, in the steric hindrance which prevents free rotation in the cavity. Strong interactions with the surface cavity seems to be excluded from bonding coefficient calculations (see below).

By evacuation at room temperature no significant variations are observed in the liquid nitrogen spectra for both copper complexes. Irreversible disappearance of the signals occur after vacuum heating above 100 °C. This findings clearly show an irreversible decomposition of the complexes probably to Cu(II) reduction.

The observed ESR spectra of the copper complexes can be interpreted on the basis of the spin Hamiltonian for \( \text{d}^9 \) ion in axial symmetry:

\[
\mathcal{H} = g_{\parallel} \beta H S_z + g_{\perp} \beta [H_x S_x + H_y S_y] + A_x S_x I_x + A_y S_y I_y + A_{\parallel} S_z I_z
\]

with \( g_{\parallel} > g_{\perp} \). Good resolution of the \( A_{\parallel} \) components was observed, while \( A_x \) components were not resolved. It is surprising that the \( \text{Cu(tmen)}(\text{OH})_2 \) ESR spectrum both in free water and in adsorbed solution is almost axially symmetrical in shape which was not expected since the coordination symmetry of this species must be lower than tetragonal. Since the linewidth of the perpendicular component is quite large, small differences in \( g_x \) and \( g_y \) might not be observed.

According to the almost axial symmetry and since in all cases \( g_{\parallel} > g_{\perp} \) we can assume for all the investigated complexes an approximate square planar configuration. We use the treatment of
Kivelson and Neiman\textsuperscript{18} based on the crystal field analysis of Maki and McGarvey\textsuperscript{19} for copper complexes. The following antibonding wave functions (in the “electron hole” notation) can be formed between the central atom 3d and the ligand 2s and 2p orbitals:

\[
\psi_{\text{B}_{1g}} = \beta_2 d_{2s,p} - \frac{1}{2} \beta_1 [-(\sigma_z^{(1)} + \sigma_y^{(2)}) + \sigma_x^{(3)} - \sigma_y^{(4)}]
\]

\[
\psi_{\text{B}_{2g}} = \beta_2 d_{xy} - \frac{1}{2} |1 - \beta_2^2| [p_x^{(1)} + p_y^{(2)}] - p_y^{(3)} - p_z^{(4)}]
\]

\[
\psi_{\text{E}_{g}} = (e d_{yz} - |1 - \varepsilon^2| [p_x^{(1)} - p_z^{(3)}])/2
\]

where the overlap integrals were included only for the \(\psi_{\text{B}_{1g}}\) wave functions, since their values for \(\psi_{\text{B}_{2g}}\) and \(\psi_{\text{E}_{g}}\) are expected to be small and negligible. The \(\sigma_0\) orbitals are sp hybridized:

\[
\sigma_{(1)} = n p^{(1)} \mp |1 - n^2| S_{(1)}
\]

with \(0 < n < 1\). The \(\psi_{\text{A}_{1g}}\) wave function was omitted since it does not affect the magnetic parameters.

The bonding coefficients in eq. (2) give a measure of the covalent character of the in-plane \(\sigma\) and \(\pi\)-bond (\(\beta_1\) and \(\beta_2\) respectively) and of the out-of-plane \(\pi\)-bond (\(\varepsilon\)). The lower are \(\beta_1\) and \(\beta_2\) values, the higher will be the covalent character of the corresponding bonds.

With the above assumptions, resolution of the spin Hamiltonian can be accomplished and equations which relate experimental ESR parameters to the bonding coefficients can be derived. The simplified equation\textsuperscript{18}:

\[
\beta_1^2 = |A_{(1)}|/P + \Delta \xi g_{\text{||}} + \frac{3}{7} \Delta g_{\perp} + 0.04
\]

(3)

can be successfully used for the \(\beta_1^2\) calculation. The P term, defined as:

\[
P = 2 \gamma_0 \beta_0 \beta_2 \langle r_k^{-3} \rangle
\]

where \(r_k\) is the nucleus-electron distance, can be assumed, according to Abragam \textit{et al.}\textsuperscript{50} to be 0.036 cm\textsuperscript{-1}. The \(\beta_2^2\) coefficient was calculated from:

\[
\xi g_{\|} - 2.0023 = \frac{8 \lambda \beta_1 \beta_2}{\Delta E_{\text{xy}}}.
\]

(4)

As suggested by several authors\textsuperscript{18, 21, 22} \(\varepsilon^2\) should be almost unity, thus indicating negligible out-of-plane covalent bonding. \(S\) and \(T(n)\) are respectively the overlap integrals for \(\psi_{\text{B}_{1g}}\) and the integrals over the ligand functions which depend on the metal-ligand distance and on sp hybridization. The values used for these quantities were taken from the values reported in the literature for oxygen and nitrogen\textsuperscript{21, 22} (for Cu(H\textsubscript{2}O)\textsuperscript{2+} and Cu(en)\textsuperscript{2+} respectively) and an average of these values for Cu(tmen)(OH)\textsubscript{2} (Table II).

The transition energies have been taken from several sources\textsuperscript{21, 23, 24} and the same values have been used either for water solution or for adsorbed species. Large variations in the transition energies are known to lead to small variations in the bonding coefficients\textsuperscript{18}.

Table II summarizes the parameters used and the calculated coefficients. These latter indicate appreciable covalency for |\(B_{1g}\)\> and |\(B_{2g}\)\> while |\(E_g\)\> orbitals result prevalently ionic in character. In other words, the in-plane \(\sigma\)- and \(\pi\)-bonds are largely covalent while the out-of-plane \(\pi\)-bond is essentially ionic. No large differences are indeed observed between adsorbed and bulk water complexes. The interaction with charged framework of the supercavity walls seems therefore to be negligible in modifying the nature of the bond, although the small differences in the coefficients of adsorbed and free charged complexes may find the explanation in this effect.

Thanks are due to the National Council of Research (CNR) for the financial support.
