Cyanocomplexes of Mercury(II), Iron(II), Cobalt(I), UV Spectra. Photochemistry

In complexes of the type [(NC)$_2$Hg$^{II}$NCFe$^{ll}$ (CN)$_3$$^{ll}$]$^{ll-}$ which are formed in aqueous mixtures of Hg(CN)$_2$ and [Fe(CN)$_6$]$_{4-}$ both metals are weakly coupled. Optical metal to metal charge transfer (MMCT) excitation from Fe$^{ll}$ to Hg$^{II}$ leads to the reduction of Hg$^{II}$ to Hg$^{I}$ an the oxidation of [Fe(CN)$_6$]$^{4-}$ to [Fe(CN)$_5$]$^{3-}$. In the complex [(NC)$_3$Co$^{II}$=Hg$^{I}$−Co$^{III}$ (CN)$_3$]$^{ll-}$ the metals are strongly coupled by direct but polar metal metal bonds. MMCT (Co$^{II}$→Hg$^{I}$) excitation induces the photoredox reaction: [HgCo$_2$(CN)$_{10}$]$^{6-}$→Hg$^{II}$ + 2[Co(CN)$_5$]$^{3-}$.

Introduction

Polynuclear transition metal complexes which contain reducing and oxidizing metal centers are characterized by optical metal to metal charge transfer (MMCT) transitions [1–8]. Two different cases can be distinguished. The interaction of the reducing and oxidizing metal may be facilitated by bridging ligands (M$_{red}$−L−M$_{ox}$) [1−8]. The electronic coupling of both metals may be very weak. Photoredox reactions induced by such MMCT transitions are well known [8, 9]. In addition, the reducing and oxidizing metal of heteronuclear complexes can be connected by a direct metal−metal bond which provides a very strong coupling of the metals. Since the interacting metal orbitals have different energies in this case the metal−metal bond has a certain degree of polarity (M−M) and MMCT transitions can occur. The extent of CT contribution to such a transition depends on the polarity of the metal−metal bond. Photoredox reactions induced by this type of inner-sphere MMCT excitation have been discussed only recently [10, 11]. In the present study we describe photoredox reactions initiated by both types of MMCT transitions. While in the system Hg$^{II}$ (CN)$_2$ [Fe$^{Il}$ (CN)$_5$]$_{3-}$ the interaction between Hg$^{II}$ and Fe$^{II}$ takes place via bridging cyanide the complex [(NC)$_3$Co$^{II}$=Hg$^{I}$−Co$^{III}$ (CN)$_3$]$^{ll-}$ contains polar Hg−Co bonds. In both cases inner-sphere MMCT (Fe$^{II}$ or Co$^{II}$ to Hg$^{I}$) excitation is associated with a redox photolysis.

Experimental Section

Materials. The compounds K$_2$[Fe(CN)$_6$]×3Hg(CN)$_2$×4H$_2$O [12] and K$_2$[HgCo$_2$(CN)$_{10}$] [13] were prepared according to published procedures. The electronic absorption spectrum of the latter complex agreed well with that reported previously [13].

Photolyses. The light source was a Hanovia 977 B-1 (1 kW) lamp. The mercury lines at 313 and 366 nm were selected by a Schoeffel monochromator GM 250/1. Solutions of the complexes were photolyzed in 1 cm spectrophotometer cells at room temperature. For quantum yield determinations the complex concentrations were such as to have essentially complete light absorption. The total amount of photolysis was limited to less than 5% to avoid light absorption by the photoproducts. Absorbed light intensities were determined by a Polytec pyroelectric radiometer that was calibrated and equipped with a RK-P-345 detector.

Progress of the photolysis was monitored by UV-visible spectral measurements with a Uvikon 860 recording spectrophotometer and a Zeiss PMQ II spectrometer for measurements at selected wavelengths.

Results

Hg(CN)$_2$/[Fe(CN)$_6$]$^{4-}$

The electronic spectrum of an aqueous solution containing Hg(CN)$_2$ and [Fe(CN)$_6$]$^{4-}$ displays a new absorption band at $\lambda$$_{max}$ = 265 nm ($\varepsilon$ = 2960). This band which does not belong to the components Hg(CN)$_2$ and [Fe(CN)$_6$]$^{4-}$ was first observed by Beck and Porzsolt in 1971 [14].

The irradiation of an aqueous solution of 0.25 M Hg(CN)$_2$ and 2×10$^{-4}$ M [Fe(CN)$_6$]$^{4-}$ into this new...
absorption band ($\lambda_{\text{irr}} = 313 \text{ nm}$) led to the deposition of metallic mercury as a dark-grey precipitate or small shiny droplets. In addition, $[\text{Fe(CN)}_6]^{3-}$ was generated and recognized by its absorption maxima at 260, 300, 320 and 418 nm. The formation of $[\text{Fe(CN)}_6]^{3-}$ was monitored by measuring the increase of extinction at 418 nm ($s = 1050$). At $\lambda_{\text{irr}} = 313 \text{ nm}$ the Fe(III) complex was formed with the quantum yield $\theta = 0.03$.

Under our experimental conditions about 70% of the incident light was absorbed by the new absorption band while both components Hg(CN)$_2$ and $[\text{Fe(CN)}_6]^{4-}$ absorbed each about 15%. Light absorption by the components does not seem to interfere with the observed photoredox reaction of the mixture. Aqueous Hg(CN)$_2$ is not light-sensitive and ligand-field excitation of $[\text{Fe(CN)}_6]^{4-}$ at 313 nm leads to a photoaquation [15].

$[\text{HgCo}_2(CO)]^{6-}$

The absorption spectrum of $[\text{HgCo}_2(CN)]^{6-}$ (Fig. 1) is dominated by a very intense long-wavelength band at $\lambda_{\text{max}} = 361 \text{ nm}$ ($\epsilon = 51200$) [13]. The complex is thermally stable only in alkaline solution. Upon irradiation at 366 nm at pH = 13 (NaOH) a very efficient photolysis took place. The photoreaction of an argon-saturated solution was accompanied by spectral changes (Fig. 1) which clearly indicated the formation of $[\text{Co(CN)}_5]^{3-}$. This complex is characterized by absorption maxima at 280 and 967 nm [16–18]. In addition, metallic mercury was formed as a grey precipitate. When the photolysis was carried out at higher concentrations of $[\text{HgCo}_2(CN)]^{6-}$ (> 10$^{-3}$ M) the mercury separated as shiny droplets. The concentration of $[\text{HgCo}_2(CN)]^{6-}$ was monitored by measuring the extinction at the band maximum at 361 nm. The complex disappeared with a quantum yield of $\theta = 0.36$ at $\lambda_{\text{irr}} = 366 \text{ nm}$.

**Discussion**

$\text{Hg(CN)}_2/[\text{Fe(CN)}_6]^{4-}$

Beck and Porzsolt have presented convincing evidence that in aqueous mixtures of Hg(CN)$_2$ and $[\text{Fe(CN)}_6]^{4-}$ polynuclear complexes of the type [(NC)$_2$Hg$^{II}$-NCFe$^{II}(CN)_2$]$^{4-}$ are formed [14]. Mercury(II) is well known for the expansion of its coordination number from 2 to 3 and 4. The presence of bridging cyanide is also apparent from the IR spectrum of the solid addition compound K$_4[\text{Fe(CN)}_6] \times 3 \text{Hg(CN)}_2 \times 4 \text{H}_2\text{O}$ [12]. The CN stretching vibration of Hg(CN)$_2$ at 2190 cm$^{-1}$ [19] and $[\text{Fe(CN)}_6]^{4-}$ at about 2050 cm$^{-1}$ [19] appears also in the addition compound which, however, shows a further band at 2070 cm$^{-1}$. This band which is blue-shifted with regard to $[\text{Fe(CN)}_6]^{4-}$ is a good indication for the presence of bridging cyanide [20–22]. Since the energy of the terminal cyanides is not changed by the formation of the bridged complex mercury and iron interact only weakly.

The assumption that the electronic coupling of both metals of the Hg$^{II}$NCFe$^{II}$ moiety is only weak is also supported by other observations. The stability constant for the association of Hg(CN)$_2$ and $[\text{Fe(CN)}_6]^{4-}$ is rather small (K = 240 M$^{-1}$) [14]. In addition the electronic spectrum of $[\text{Fe(CN)}_6]^{4-}$ remains essentially unaffected by the presence of Hg(CN)$_2$ with the exception of the new absorption band at $\lambda_{\text{max}} = 265 \text{ nm}$. This new band is logically assigned to the MMCT transition from the $d_1$ orbitals of the reducing Fe(II) to the 6$s$ orbital of the oxidizing Hg(II). This assignment is also supported by the fact that the electronic spectra of mixtures of Hg(CN)$_2$ and other transition metal cyano complexes such as $[\text{Ru(CN)}_6]^{4-}$, $[\text{Mo(CN)}_6]^{4-}$, $[\text{Fe(CN)}_6]^{3-}$, $[\text{Mo(CN)}_6]^{3-}$, $[\text{Ni(CN)}_4]^{2-}$, $[\text{Rh(CN)}_6]^{3-}$, and $[\text{Pd(CN)}_4]^{2-}$ display MMCT absorptions only if the transition metal is reducing (Ru(II) and Mo(IV)).

H. Kunkely et al. • Photoredox Reactions of Hg(CN)₂/[Fe(CN)₆]⁴⁻ and [HgCo₂(CN)₁₀]⁶⁻

[14]. In the case of [Ru(CN)₆]⁴⁻ the MMCT band occurs at \( \lambda_{\text{max}} \approx 238 \text{ nm} \). Such a blue shift from Fe(II) to Ru(II) is expected since [Ru(CN)₆]⁴⁻ is the weaker oxidant compared with [Fe(CN)₆]⁴⁻ [23].

Upon MMCT (Fe¹¹ to Hg¹¹) excitation an aqueous mixture of Hg(CN)₂ and [Fe(CN)₆]⁴⁻ underwent a photoredox reaction according to the equation:

\[
\text{Hg(CN)₂} + 2[\text{Fe(CN)₆}]⁴⁻ \rightarrow \text{Hg}^0 + 2\text{CN}^- + 2[\text{Fe}^{III}(\text{CN})₃]⁻
\]

The mechanism of this reaction was not investigated. However, the following sequence of processes may lead to product formation:

1. \([\text{NC}_2]\text{Hg}^{III}\text{NCFe}^{III}(\text{CN})₃]⁻ \rightarrow \text{hv}\) \( \quad (\text{1})\)
2. \([\text{NC}_2]\text{Hg}^{III}\text{NCFe}^{III}(\text{CN})₃]⁻ \rightarrow \text{Hg}^0 + \text{CN}^- + [\text{Fe}^{III}(\text{CN})₃]⁻ \) \( \quad (\text{2})\)
3a. \([\text{Hg}^0 + \text{CN}^- + [\text{Fe}^{III}(\text{CN})₃]⁻ \rightarrow \text{Hg}^0 + \text{CN}^- + [\text{Fe}^{III}(\text{CN})₃]⁻ \) \( \quad (\text{3a})\)
3b. \(2\text{HgCN} \rightarrow \text{Hg}^0 + \text{Hg}^0 + \text{Hg}^0 + \text{Hg}^0 (\text{CN})₂ \) \( \quad (\text{3b})\)

Mercury(I) cyanide is not stable but could exist as a reactive intermediate [19]. It may oxidize Fe(II) (3a) or disproportionate to Hg(0) and Hg(II) (3b).

\([\text{HgCo}_2(\text{CN})₁₀]^{6⁻}\)

The structure of [HgCo₂(CN)₁₀]⁶⁻ is not known. But there is little doubt that the trinuclear complex contains a linear Co—Hg—Co moiety in analogy to many other related compounds [24] including [HgCo₂(CO)₈] [25]. The metal—metal bonds are assumed to be polar. Consequently, the oxidation numbers Co(I) and Hg(II) can be assigned. This assumption is based on the following considerations. Generally, the frequency of the cyanide stretching vibration of cyano complexes decreases with decreasing charge of the metal ion reflecting an increased \( \pi \)-back bonding in this direction. In the IR-spectra of homoleptic cobalt cyanide complexes the lowest-frequency CN bands appear at \(\sim 2130 \text{ cm}^{-1}\) for Co(III) and \(\sim 2080 \text{ cm}^{-1}\) for Co(II) [19].

Although [Co(III)]³⁺ or [Co(IV)]³⁺ seem to exist [19, 26] these complexes have never been characterized and their IR spectra are also not known. The complex [HgCo₂(CN)₁₀]⁶⁻ exhibits CN bands at 2035, 2072, 2099, and 2128 cm⁻¹ [13]. By comparison with Co(III) and Co(II) it is then certain-ly reasonable to assign the oxidation numbers [Hg²⁺Co²⁺(CN)₁₀]⁶⁻.

The metal—metal interaction of [HgCo₂(CN)₁₀]⁶⁻ can be explained by a qualitative MO diagram (Fig. 2). The frontier orbitals are generated by the overlap of the 6s Hg and 3d² Co orbitals of the linear Co—Hg—Co moiety which is located on the z-axis. The 6s(Hg)—3d²(Co) energy difference determines the bond polarity. The 6s orbital of mercury occurs at rather high energies [27] and is certainly situated above the dz² orbital of Co. It follows that the metal—metal bond is polar: Co—Hg—Co. The bonding electron pair is then predominantly localized at both Co atoms. This description confirms also the assignment of the oxidation numbers Hg(II) and Co(I). However, in distinction to the system Hg(CN)₂/[Fe(CN)₆]⁴⁻ the electronic coupling of the metals in [HgCo₂(CN)₁₀]⁶⁻ is rather strong due to the direct orbital overlap.

![Fig. 2. Qualitative MO diagram of the linear Co-Hg-Co moiety (D₅h symmetry) of [HgCo₂(CN)₁₀]⁶⁻.](image)

According to the MO scheme (Fig. 2) the lowest-energy electronic transition of [HgCo₂(CN)₁₀]⁶⁻ from \( \sigma^* \) to \( \sigma^+ \) has a MMCT contribution. Although the extent of this contribution is not known in a limiting description the \( \sigma^* \rightarrow \pi^* \) transition can be viewed as a Co(I) to Hg(II) MMCT transition. This MMCT transition which is allowed (2U +— >2g +  in D₅h symmetry) is then logically assigned to the intense long-wavelength absorption of [HgCo₂(CN)₁₀]⁶⁻.

Upon MMCT excitation an efficient photolysis takes place according to the equation:

\([\text{Hg}^{II}\text{Co}^{II}_2(\text{CN})₁₀]^{6⁻} \rightarrow \text{hv} \quad \text{Hg}^0 + 2[\text{Co}^{II}(\text{CN})₃]⁻\)

The mechanism of this reaction was not investigated. It is feasible that this stochiometry represents also the primary photoprocess which proceeds as a reductive elimination at Hg(II) in a concerted fash-
As an alternative the photolysis may first generate intermediates which are formed by the homolytic cleavage of one Hg—Co bond:

$$[\text{Hg}^{II}\text{Co}^{III}(\text{CN})_{5}]^{3-} \rightarrow \text{Hg}^{0} + [\text{Co}^{II}(\text{CN})_{5}]^{3-}$$

The final product formation could then take place by the thermal splitting of the second Hg—Co bond:

$$[\text{Hg}^{II}\text{Co}(\text{CN})_{5}]^{3-} \rightarrow \text{Hg}^{0} + [\text{Co}^{II}(\text{CN})_{5}]^{3-}.$$

**Conclusion**

The system Hg(CN)$_2$/[Fe(CN)$_6$]$^{4-}$ and [HgCo$_2$(CN)$_{10}$]$^{6-}$ adds further evidence to the general significance of photoredox reactions of cyanide-bridged complexes induced by inner-sphere MMCT excitation. A new type of inner-sphere MMCT transition occurs in the trinuclear complex [(NC)$_5$Co$_{11}$Hg$_{11}$Co(CN)$_5$]$.^{1-}$. In this case the reducing and oxidizing metal are connected by a direct metal—metal bond. MMCT excitation leads also to a photoredox reaction.
