Rhodium(III) Complexes, Bis-amide Ligands, IR Spectra, 1H NMR Spectra, Cyclic Voltammetry

Synthetic procedures are described that allow access to a number of new Rh(III) complexes with the tetradeutate bis-amide ligand N,N'-bis(2'-pyridinecarboxamide)-1,8-naphthalene (LH2). These complexes have the formulae Rh(LH2)Cl3, Na[RhLX2] • H2O (X = Cl, CN) and [RhLA2]C104 (A = pyridine, 1-methylbenzotriazole). The compounds have been characterized by elemental analyses, conductivity measurements, X-ray powder patterns, spectroscopic (IR, UV/VIS, 1H NMR) studies and electrochemical methods. The neutral amide behaves as a bidentate ligand in the oligomeric or polymeric, octahedral complex Rh(LH2)Cl3. Monomeric, trans octahedral structures are assigned for the complexes of L2 in the solid state; the doubly deprotonated ligand acts as a tetradeutate chelating agent with the four nitrogens as ligating atoms.

1. Introduction

The coordination chemistry of organic amide ligands plays an important role in inorganic chemistry [1], ranging from solution chemistry [2, 3] to biological modeling [4, 5] and materials chemistry [6, 7]. In contrast to the large number of studies concerning 3d metal-amide complexes, little is known about the corresponding complexes with 4d and 5d metals [1]; exceptions are Pd(II) and Pt(II) complexes.

As part of our systematic investigation on the coordinating properties of the amide bond [8–18], we report here the preparation and detailed characterization of rhodium(III) complexes with the bis-amide tetradentate ligand N,N'-bis(2'-pyridinecarboxamide)-1,8-naphthalene (L, LH2). Until now, with the exception of the work of Che and co-workers [19], no Rh(III) complexes with bis-amide ligands have been investigated. One of the driving forces behind our current interest in rhodium-amide chemistry is the fact that dianionic, pyridine-containing, bis-amide ligands are capable of stabilizing transition-metal ions in high oxidation states [2, 19, 20]; the exciting possibility to generate stable Rh(IV) species was one of the stimuli for this work. The ligand LH2 has been shown to coordinate to 3d [21–24], Pd(II), Pt(II) [25] and 4f [26, 27] metals in several modes, largely determined by the nature of the metal and the anion present, and by the preparative conditions.

2. Experimental

All synthetic operations were performed under aerobic conditions. The starting material RhCl3 • 3H2O was purchased from Merck. LH2 was synthesized as described earlier [21]; its purity was checked by microanalyses and 1H NMR spectroscopy. The solvents and chemicals used were of reagent grade, without further purification. In electrochemical work, MeCN was dried and distilled over powdered CaH2. N Bu4BF4 (Merck) was dried at 95 °C in a vacuum for 48 h before use. All solutions for electrochemical studies were deaerated with high-purity Ar. Physicochemical measurements and spectroscopic techniques were carried out by published methods [15, 28, 29].

A solution of RhCl₃·3H₂O (0.26 g, 1.0 mmol) in MeOH (25 ml) was added dropwise to a stirred warm solution of LH₂ (0.37 g, 1.0 mmol) in the same solvent (30 ml). Upon addition of the metal salt a yellow precipitate was formed. Stirring was continued for 12 h at room temperature. The precipitate was filtered off, washed with EtOH (2×5 ml) and Et₂O (3×10 ml), and dried in vacuo over silica gel. Yield: ca. 95%.

Analyses for C₂₂H₁₆N₄O₄RhCl₃
Calcd C 45.74 H 2.80 N 9.70 Cl 18.41%,
Found C 46.03 H 2.71 N 9.63 Cl 17.93%.

The molar conductance (Λm) value for a ca. 1×10⁻³ M DMSO solution at 25 °C was 34 S cm² mol⁻¹.

Na[RhCl₂(H₂O)] (2)
LH₂ (0.37 g, 1.0 mmol) was slowly added to a solution of RhCl₃·3H₂O (0.26 g, 1.0 mmol) in MeOH (30 ml). A yellow precipitate was immediately obtained. The reaction mixture was stirred while a solution of NaOH (0.08 g, 2.0 mmol) in H₂O (5 ml) was added in small portions over approximately 10 min; during the alkali addition the colour changed to red. Overnight reflux gave a red-orange precipitate, which was collected by filtration and redissolved in MeCN (30 ml). Layering of this solution with an equal volume of Et₂O gave, after several days, orange-red flakes, which were isolated by filtration, washed with Et₂O and dried in air. Yield: ca. 35%.

Analyses for C₂₁H₁₈N₄O₅RhNaCl₂
Calcd C 45.46 H 2.78 N 9.64 Cl 12.20%,
Found C 45.33 H 2.69 N 9.80 Cl 13.01%.

Λm(MeCN, 10⁻³ M, 25 °C): 128 S cm² mol⁻¹.

[RhL(CN)₂]ClO₄ (4)
A slurry of complex I (0.25 g) in EtOH (50 ml) was treated with an excess of pyridine (Py) (1.2 ml) and Zn powder (0.12 g). The reaction mixture was heated for 15 min at 55 °C and evaporated to dryness. The crude product was extracted into CHCl₃–MeOH (ca. 40:60, v/v), the solution filtered and an excess of LiClO₄·3H₂O, dissolved in the minimum volume of MeOH, added. After overnight storage in a freezer, the resulting orange powder was collected by filtration, washed with Et₂O and dried in vacuo. The product was purified by two cycles of dissolution in MeCN and precipitation by Et₂O. Yields were typically in the 20–30% range.

Analyses for C₂₂H₂₄N₆O₆RhCl
Calcd C 52.87 H 3.33 N 11.56%,
Found C 53.01 H 3.48 N 11.17%.

Λm(MeCN, 10⁻³ M, 25 °C): 128 S cm² mol⁻¹.

[Rh(II)₂(H₂O)]ClO₄ (5)
This orange solid was prepared by reacting compound I (0.25 g, 0.43 mmol) with excess 1-methylbenzotriazole (II, Mebta) and LiClO₄·3H₂O, in the presence of Zn powder (0.12 g) and the strictly stoichiometric (for the removal of the two amide hydrogens of LH₂) amount of Py (0.07 ml, 0.87 mmol) in a manner similar to the procedure described above for 4. The product was isolated and purified using the same solvents and procedures as above. Yield: ca. 20%.

Analyses for C₂₆H₂₄N₁₀O₆RhCl
Calcd C 51.77 H 3.39 N 16.78%,
Found C 51.91 H 3.50 N 15.99%.

Λm(MeCN): 119 S cm² mol⁻¹.

To a solid mixture containing complex 2 (0.25 g, 0.43 mmol) and excess NaCN (0.10 g, 2.05 mmol) was added MeOH (40 ml). The resulting orange slurry was refluxed for a few hours to yield an intense yellow solution and some white precipitate. The latter was removed by filtration and the filtrate refrigerated (−20 °C) for 48 h. The resulting yellow microcrystalline solid was collected by filtration and washed with Et₂O. The solid was purified by dissolution in MeOH (30 ml), followed by filtration, addition of 30 ml of acetone-Et₂O (50:50, v/v), and overnight storage of the solution at −5 °C. The product was isolated by filtration, washed with n-hexane and dried in air. Yield: ca. 40%.

Analyses for C₂₂H₁₆N₆O₃RhNaCl₂
Calcd C 51.26 H 2.87 N 14.95%,
Found C 51.01 H 2.96 N 14.27%.

Λm(MeCN, 10⁻³ M, 25 °C): 140 S cm² mol⁻¹.

Λm(MeOH, 10⁻³ M, 25 °C): 74 S cm² mol⁻¹.
Caution! Perchlorate salts are potentially explosive. Although no detonation tendencies have been observed in the synthetic work, caution is advised and handling of only small quantities is recommended.

3. Results and Discussion

The Experimental Section lists five Rh(III) complexes in order of time of their preparation. The formation of some representative compounds can be summarized in eq. (1)–(3):

\[
\begin{align*}
\text{nRhCl}_3 \cdot 3 \text{H}_2 \text{O} + \text{nLH}_3 & \xrightarrow{\text{MeOH}} \{(\text{Rh} \text{(LH}_2) \text{Cl}_2 \text{Cl}\}_\text{n} + 3\text{nH}_2 \text{O} \\
\text{RhCl}_3 \cdot 3 \text{H}_2 \text{O} + \text{LH}_2 + 2\text{NaOH} & \xrightarrow{\text{MeOH-H}_2 \text{O reflux}} \text{Na[RhLCL] \cdot H}_2 \text{O} + \text{NaCl} + 4\text{H}_2 \text{O} \\
\{(\text{Rh} \text{(LH}_2) \text{Cl}_2 \text{Cl}\}_\text{n} + \text{4nPy} + \text{nLiClO}_4 \cdot 3\text{H}_2 \text{O} & \xrightarrow{\text{EtOH-MeOH-CH}_2 \text{Cl}_2.} \text{Zn, exc. Py} \\
\text{n[RhL(Py)_2]ClO}_4 + \text{nLiCl} + 2\text{nPyHCl} + 3\text{nH}_2 \text{O} & \text{(4)}
\end{align*}
\]

A few synthetic points deserve comments. First, the nearly quantitative yield in the preparation of 1 is a strong evidence that this compound is oligomeric or polymeric. Second, it appears that the anions trans-[RhLCl] \text{Cl} \text{]}^- is the thermodynamically preferred species in aqueous methanol (at \text{~} neutral \text{pH}) in the absence of strong axial ligands, which can be used as a starting material for the synthesis of analogous products. For example, we anticipated that complex 2 should undergo chloro substitution on treatment with an excess of strong axial ligands and have confirmed this by preparing complex 3. Third, in the syntheses of the cationic complexes 4 and 5 the reaction is accelerated by the presence of \text{Zn} powder; presumably, a \text{Rh(I)} species generated in situ catalyzes the substitution reactions. This parallels the behaviour observed for the Rh(III)/1,2-bis(2'-pyridinecarboxamido)benzene/Py complexes \text{[19]}. A final point of interest is the use of LiClO\text{4} in the preparation of 4 and 5. The use of LiClO\text{4} as the source of counterions, instead of NaClO\text{4} or KClO\text{4}, gives good results because LiClO\text{4} and LiCl (a product of the reactions) are both soluble in the solvent mixture used and, thus, 4 and 5 are not contaminated.

The isolated compounds are microcrystalline or powder-like and stable under atmospheric conditions. Complex 1 is slightly soluble only in DMSO. Complexes 2–5 are soluble in polar organic solvents, but to varying extents. The complexes have a moderate solubility in \text{H}_2 \text{O}; however, their aqueous solutions are not stable. We had hoped to structurally characterize one of the complexes of L\text{2}^- by X-ray crystallography (working mainly with MeCN and DMF), but we were thwarted on numerous occasions by twinning problems or lack of single crystals. Thus, the characterization of the complexes is based on other physical techniques and on spectroscopic methods.

The molar conductance values of 2–5 in MeCN and MeOH lie in the ranges observed for 1:1 electrolytes \text{[30]}. The \text{\Lambda}_\text{M} value of 1 in DMSO is also in accord with this compound being formulated as a 1:1 electrolyte \text{[30]}. X-ray powder diffraction patterns in the \text{4}° < 2\theta < 60° range indicate that each solid represents a definite compound, which is not contaminated with starting materials or/byproducts.

All the prepared complexes are diamagnetic.

The thermal decomposition of the complexes was studied using TG/DTG, DTA and DSC techniques. The TG/DTG curves of 2 and 3 show a first, endothermic mass loss at \text{80}–\text{125} and \text{70}–\text{115} °\text{C}, respectively, which corresponds to the release of the water content; the relatively low temperature of \text{H}_2 \text{O} loss indicates that this is lattice held. Clear plateaux are reached at about 130 and 120 °\text{C} for 2 and 3, respectively, suggesting that the anhydrous species are thermally stable. The activation energy values \text{E}_\text{a} of the dehydration reactions were

\[
\text{Na[RLX}_x \cdot \text{H}_2 \text{O} \xrightarrow{T} \text{Na[RLX}_x \cdot \text{H}_2 \text{O} (4) (X = \text{Cl, CN})}
\]
determined by the variable heating rate method proposed by Flynn and Wall \text{[31]}; full experimental details of this method have also been given in ref. 32. The average \text{E}_\text{a} values are 69.4 KJ mol\text{−1} for 2 and 57.5 KJ mol\text{−1} for 3. These values are characteristic of the removal of crystal water \text{[11,14,33]}. By differential scanning calorimetry (DSC) at a heating rate of 5 °\text{C} min\text{−1} we have also measured the enthalpy of dehydration of 2 and 3. The \text{ΔH} values were found to be 31.6 (2) and 26.9 (3) KJ mol\text{−1}; these values are in the region expect-
ed for the removal of crystal H₂O [11, 14, 34]. The complexes decompose above ca. 280 °C with rather simple degradation mechanisms, as revealed by the small number of DTG peaks, and without formation of stable intermediates; however, compound 5 explodes at ca. 250 °C.

Table I gives diagnostic IR and far-IR bands. The assignments have been made by comparison with the data obtained for metal complexes with the same [21-27] or similar [8-18, 35, 36] ligands; the assignments for LH₂ and complex 1 were assisted by deuterium isotopic substitution, which highlights any absorption associated with the N-H bonds. Assignments of metal-ligand stretching vibrations have been made by noting: (i) the frequencies of the internal modes of LH₂, Py and Mebta in the far-IR region; (ii) the variation in band frequency with changing the axial ligand in 2-5, and (iii) extensive literature reports [37-39].

In the ν(OH)water region, the spectra of 2 and 3 show one medium and continuous absorption covering the 3500-3300 cm⁻¹ region, which is attributed to the presence of lattice water [40]. Dehydration of these complexes at ca. 150 °C causes the disappearance of the band confirming its origin.

The perchlorate compounds 4 and 5 show very strong bands due to the ν(F₂) and ν(C=O) modes of the uncoordinated (ionic) T₄ClO₄⁻ near 1100 and 620 cm⁻¹, respectively [37].

The IR spectrum of Mebta exhibits two bands at 1197 and 1110 cm⁻¹, which can be associated with the ν(N=N) and ν(N-N) modes of vibration, respectively [41]. These bands are shifted to higher frequencies in 5. Both shifts are compatible with N(3) of Mebta being the donor atom to rhodium(III) [41].

The IR spectrum of LH₂ shows the characteristic bands of trans secondary amide groups with 2-pyridyl residues [22]. The absence of large shifts of the ν(N=H) and amide V bands in the spectrum of 1, in comparison with these bands in LH₂, confirms the inability of the amide nitrogen to participate in coordination, if non-deprotonated. The amide I band shifts to a lower frequency, while the amide II and III bands shift to higher frequencies in 1; these shifts indicate amide-O coordination.

² Fourier-transform spectra; ² ν(CO); ³ in secondary amides these bands arise from ν(C=N) and δ(NH) modes; ⁴ π(NH); ⁵ overlapping with a ligand band; ⁶ overlapping, vs = very strong, s = strong, m = medium, w = weak, b = broad, γ = out-of-plane deformation, δ = in-plane deformation. ν(Rh-Cl), is the stretching vibration of the terminal Rh-Cl bond, Py = pyridine and Mebta = 1-methylbenzotriazole.
[35,36]. Differences between the spectra of 1 and 2–5 are readily observable. Importantly, the v(N–H) and amide V bands are absent in the spectra of 2–5, as expected from the stoichiometry. In addition the amide II and III peaks have been replaced by a strong band at ca. 1390 cm⁻¹, which is characteristic for deprotonated secondary amide complexes [11,25,35,36]. This replacement is to be expected, as the removal of the amide proton produces a pure C–N vibrational stretching mode. As has been shown previously for complexes of neutral secondary amides [35], the presence of both coordinated and uncoordinated amide groups in a compound is indicated by the considerably more complicated IR spectrum obtained. The observation of only one sharp absorption for each amide I, II and III band in the spectrum of 1 indicates that both amide groups are coordinated.

In the spectra of 1, 2, 3 and 5, the in-plane and out-of-plane deformation bands of the 2'-pyridyl ring shift to higher frequencies to indicate coordination of both ring N-atoms [42]. These characteristic bands are doubled in the spectrum of 4, due to the presence of two different pyridine rings. Since the four bands are significantly shifted to higher frequencies from their positions in the free LH₂ and Py spectra, the implication is that all heterocyclic nitrogens of 4 are coordinated [11,16].

The spectrum of 3 exhibits the ν(C≡N) mode in the region characteristic of terminal C-bonded cyano groups [37]. In addition to this mode, the cyano complex exhibits the ν(Rh–C) band in the low frequency region; the frequency of the ν(Rh–C) mode is consistent with an octahedral environment around the metal [37,39]. The very strong bands at 327 and 324 cm⁻¹ in the far-IR spectra of 1 and 2, respectively, arise from the terminal Rh³⁺–Cl stretching vibration in an octahedral environment [37,39]. It is quite clear that the position of ν(Rh–Cl) rules out the possibility of bridging chloro ligands [39]. The appearance of one ν(Rh–Cl), in each spectrum indicates that the two chloro ligands are trans to each other [37]. The presence of two ν(Rh–Namide) and two ν(Rh–Nring) vibrations in the far-IR spectra of 2–5 confirms the cis arrangements of the amide and 2'-pyridyl nitrogens in the equatorial plane of these complexes [37].

Table II gives details of the solid-state electronic spectra and diagnostic ¹H NMR chemical shifts for the prepared complexes. The electronic spectra of Rh(III) complexes all show bands at 21870–24570 and 26770–32400 cm⁻¹; the spectra resemble those of other six-coordinate rhodium(III) compounds and are assigned as transitions from the ¹A₁₈ ground state to the ¹T₁₂ g and ¹T₂₈ upper states in octahedral symmetry, in increasing order of energy [38,43]. The higher energy band is probably obscured by change-transfer absorptions and hence crystal field parameters can not be calculated [43]. The complexes 4 and 5 seem to exhibit a splitting of the first spin-allowed band; this splitting is characteristic of a tetragonal distortion arising from the different nature of L₂⁻ and Py or Mebta [43]. However, an ¹A₁₈→³T₂₈ (singlet-triplet, spin-forbidden transition) origin of the lower energy component of the visible band can not be ruled out [43].

The ¹H NMR study was based on comparison with the data obtained for diamagnetic complexes with the same [25] or similar [19,35,36] ligands; as-

Table II. Characteristic solid-state electronic (10³ cm⁻¹) and ¹H NMR (ppm) spectral data.

a Diffuse reflectance spectra; b spectra recorded at ambient temperature; c assignments are given assuming a ligand field of O₆ symmetry; d chemical shifts with reference to Me₄Si in d₆-DMSO (1–3) or CD₃CN (4,5) solutions; e the spectra were run 15–20 min after dissolution; f coupling constants in Hz. b = broad, d = doublet, sh = shoulder.
signments for individual ring protons in 4 and 5 were also assisted by resonance decoupling studies. The occurrence of the NH signals at almost the same δ values in the spectra of 1 (10.34 ppm) and free LH₂ (10.52 ppm) in d₆-DMSO indicates the non-involvement of the neutral amide nitrogens in coordination; a large downfield shift would be expected if coordination had occurred.

As compared to the spectrum of free LH₂ in various solvents, the naphthalene and 2'-pyridyl signals in the spectra of the complexes are slightly shifted to lower or higher fields; the changes in chemical shifts are due to several effects, like the electric field caused by complexation, π-bonding and temperature-independent paramagnetism of the metal ion [44]. The most pronounced variation in chemical shift is the downfield shift of H(6)' (in free LH₂ this signal appears at δ 8.54 and 8.56 ppm in d₆-DMSO and CD₃CN, respectively) indicating the participation of the nearest nitrogen atoms N(1') in metal coordination [25, 35, 36]. For complexes 2–5, chemical shifts and coupling constants of naphthalene protons were found to be completely unaffected by the nature of the axial ligand.

The spectra of 4 and 5 are much more complicated than those of 1, 2 and 3 due to the presence of Py and Mebta as axial ligands. With regard to compound 5, the ¹H NMR spectrum of free Mebta in CD₃CN shows signals at δ 4.34(s), 7.45(t), 7.59(t), 7.84(d) and 8.03(d) due to CH₃, H(5), H(6), H(7) and H(4), respectively [45]. The signal of H(4) shifts downfield (ca. 0.25 ppm) compared with the free triazole, suggesting that the azole-N(3) atom is coordinated to Rh(III) [45].

Complexes 2, 3 and 4 were studied by using the cyclic voltammetry (CV) technique in MeCN. Data are summarized in Table III. Unfortunately, the insoluble nature of the rhodium complex of neutral LH₂ prevented comparison with the CV data of the deprotonated complexes. Complex 5 displayed complicated, broad, ill-defined and irreversible features, presumably because of the non-innocent redox behaviour of Mebta.

The CV examination of 2 in MeCN reveals the presence of two oxidation couples at +0.37 and +0.94 V (vs. ferrocene/ferrocenium) and one reduction couple at Eₓ of −2.00 V. The peak separation ΔEₓ for each oxidation couple is close to that anticipated for a Nerstian one-electron process (59 mV); plots of peak current vs. v (v = scan rate) in the 20–200 mV s⁻¹ are linear, and the ratio of the cathodic to anodic peak currents is very close to one, indicating that electron transfer is reversible and that mass transfer is limited [46]. The reduction couple (Rh₃⁻ + e⁻ → Rh₃++) is irreversible. Complexes 3 and 4 show a similar CV behaviour; however, the second oxidation reaction is irreversible. The increase in the oxidation potential values parallels the increase in the charge on the complex from −1 to +1. Complexes 2 and 3, which bear the same charge, have a small difference in the formal oxidation potential. This probably indicates the dominance of the potential-energy terms over the effect of the donor strength of the axial ligands [19].

The relative insensitivity of the first oxidation couple of the anionic complexes 2 and 3 to the nature of the axial ligand, the high stability of their one-electron oxidized products and literature reports [19] for Rh(III) complexes with similar di-anionic, pyridine-containing, bis-amide tetradeinate ligands suggest that the first oxidation couple

* Cyclic voltammograms were recorded using a standard three-electrode assembly (glassy-carbon working, Pt-wire auxiliary, SCE reference) and 0.1 M NBu₄BF₄ as supporting electrolyte; b the scan rate was 100 mV s⁻¹ and no IR compensation employed; c potentials are quoted vs. the ferrocene/ferrocenium couple; d E₀ is given for reversible couples; e these potentials are reported for irreversible couples; f iₚc and iₚa are the peak currents of the first and second oxidation peaks, respectively; g iₚc and iₚₚox are the peak currents of the reduction and the first oxidation couple, respectively.
is largely ligand- and not metal-centred. Although LH₂ only gives an irreversible oxidation peak at a much more anodic potential (ca. 1 V vs. ferrocenium-ferrocene), it has been established [19] that coordination to metal and deprotonation of the amide groups can cause analogous ligands to be oxidized at a less anodic potential. Che and co-workers [19] have shown that the axial ligand exerts its effect through the central metal electron density which in turn affects the energy levels and electron density on the equatorial ligand; thus, the redox oxidation couple is mainly ligand-centred but has a certain degree of metal character. The second oxidation couple of 2, 3 and 4 is attributed to \( \text{Rh}^{III} \rightarrow \text{Rh}^{IV} + e^- \), with the generated Rh(IV) species being unstable. Efforts to characterize the one- and two-electron oxidized species using ESR and UV/VIS spectroscopies are in progress.

From the overall study presented above, it is concluded that 1 almost certainly has the oligomeric or polymeric, octahedral structure shown in III. Thus each molecule of LH₂ would act as a bis-bidentate ligand coordinating through both pyridyl-N and amide-O atoms and bridging two metal ions. Molecular models show that such a structure is quite feasible. This form of coordination would allow a considerable amount of hydrogen bonding, accounting for the low solubility of this ionic complex. Although \textit{trans} conformations of the four ligand donor atoms can not be discounted, the appearance of two \( \nu(\text{Rh} - \text{N}_\text{ring}) \) and two \( \nu(\text{Rh} - \text{O}_\text{amide}) \) bands in the far-IR spectrum suggests a \textit{cis} arrangement.

Complexes 2–5 have a low-spin, monomeric octahedral stereochemistry (IV). The nitrogen atoms of the chelating tetradentate dianionic ligand \( \text{L}_2^- \) seem to adopt an essentially planar arrangement about rhodium(III), with the remaining axial coordination sites occupied by chloro(2), cyano(3), pyridine(4) or 1-methylbenzotriazole(5) ligands. Amide deprotonation leads to systems having a considerable degree of delocalization.

The results described in this report represent the initial study of the coordination chemistry of polydentate amide ligands with 4d and 5d metals; further studies are in progress and iridium and gold species at various oxidation states are under characterization.

We wish to thank Prof. H. O. Desseyn and Prof. N. Hadjiliadis for providing some instrumental facilities (thermal, far-IR) and elemental analyses, respectively. We also thank Dr. J. C. Plakatouras for assistance and useful advice with cyclic voltammetry and NATO for partial support of this work.
