Biominalerization, Silica, Silicon-Accumulating Plants

A series of silicon-accumulating plants [different Equisetum (horse tail) species, Echium vulgare, and Symphytum officinale] were studied by solid-state $^{29}$Si NMR experiments. For this purpose, selected parts of these plants were freeze-dried and then investigated by solid-state $^{29}$Si VACP/MAS NMR spectroscopy. The $^{29}$Si NMR spectra of these plants are quite similar and exhibit the typical pattern characteristic of polysilicic acid (amorphous silica).

Introduction

It has been generally accepted that silicon is an essential element for many biological systems, being required for the production of structural materials and/or metabolic processes (see for example ref. [1], and literature cited therein). Biominalerized silica (biosilica) of the general formula type [SiO₄]ₙ(2OH)ₙ₋ₙ (n = 0 to 4) has been recognized to have a structural function in certain marine organisms (such as diatoms, silicoflagellates, radiolarians, and sponges) and silicon-accumulating plants [such as Equisetum (horse tail) species]. As shown by various physical methods (including high-resolution transmission electron microscopy [2], solid-state $^{29}$Si NMR spectroscopy [2], and Si K XANES spectroscopy [3]), the structural nature of biosilica is best described as an amorphous material. However, some kind of mid-range ordering at a length-scale of 4 - 10 Å has been claimed for silicas isolated from rice husks (Oryza sativa) [3]. Here we report on the application of solid-state $^{29}$Si VACP/MAS NMR spectroscopy (VACP = Variable Amplitude Cross Polarization) to the structural investigation of biogenic silica deposits of plants [4]. This particular method allows a direct structural characterization of the biosilica without its isolation and enrichment [5]. The plants examined in this study were a series of Equisetum species, Echium vulgare, and Symphytum officinale.

Experimental Section

Different parts of the plants investigated (see Table 1) were separated mechanically and subsequently freeze-dried. The synthetic silica was purchased from Merck (silica gel 60; particle size, 0.015 - 0.040 mm). All samples were studied by solid-state $^{29}$Si VACP/MAS NMR spectroscopy. For this purpose, the samples were measured at 23 °C on a Bruker DSX-400 NMR spectrometer with bottom layer rotors (ZrO₂; diameter, 7 mm) containing ca. 200 mg of sample [$^{29}$Si, 79.5 MHz; spinning rate, 5 - 7 kHz; contact time, 5 ms; 90° $^1$H transmitter pulse length, 3.6 μs; repetition time, 4 s; number of scans, 22000 - 150000; external standard, TMS ($\delta = 0$)].

Results and Discussion

The biosilica deposits of the silicon-accumulating plants Equisetum arvense, Equisetum giganteum, Equisetum hyemale, Equisetum palustre, Equisetum telmateia, Echium vulgare, and Symphytum officinale were structurally characterized by solid-state $^{29}$Si NMR experiments. For this purpose, certain parts of these plants (see Table 1) were separated and freeze-dried and then investigated by $^{29}$Si VACP/MAS NMR spectroscopy. For reasons of comparison, synthetic silica was also studied by this method.

The $^{29}$Si NMR spectra obtained in these studies look quite similar for all plants. Fig. 1 (leaves

Fig. 3. Solid-state $^{29}$Si VACP/MAS NMR spectrum of synthetic silica (spinning rate, 5 kHz; number of scans, 2072; for further details, see Experimental Section).

Ordinated silicon (in SiO$_4$ units) is present in all samples. The spectra show the well known pattern typical of amorphous silica (Fig. 3) with resolved Q$^2$, Q$^3$, and Q$^4$ groups and do not exhibit hints for the presence of penta- and hexacoordinate silicon, although the existence of pentacoordinate silicon (SiO$_5$ units) cannot totally be excluded [6].

It should be mentioned that the ratio of the Q$^2$, Q$^3$, and Q$^4$ moieties in the biosilica samples studied does not correspond to the intensity ratio of the respective resonance signals in the spectra, because the VACP/MAS technique does not lead to quantitative spectra [7, 8]. Nevertheless, the results obtained in this study clearly demonstrate that solid-state $^{29}$Si VACP/MAS NMR spectroscopy is a valuable non-destructive method for the structural characterization of biosilica in intact biological systems. In contrast to other experimental methods reported, this particular $^{29}$Si NMR technique allows the direct investigation of intact (freeze-dried) silicon-
accumulating plants and does not need the isolation and enrichment of the biosilica by destructive methods. We are planning to extend our solid-state $^{29}$Si NMR studies to biosilica deposits of marine organisms, such as diatoms, radiolarians, and sponges.

Acknowledgements

This work was supported by the Fonds der Chemischen Industrie. We thank the Botanischer Garten, Julius-von-Sachs-Institut für Biowissenschaften, Universität Würzburg, for providing us with plant materials.

[5] The solid-state $^{29}$Si NMR studies described in ref. [2] were not performed with the VACP/MAS technique and the biosilica samples investigated were isolated from the plants.
[8] Because of the poor signal to noise ratio, contact time depending or quantitative NMR experiments were not performed.
